The Evolutionary Tracks for Low to High Mass Star Formation through Variable Accretion Models

by David HASTIE

Embedded star formation is largely obscured from even the most modern of telescopes and computational modelling can therefore provide some of the essential information required to fully understand the intrinsic star forming processes. In this research, evolutionary models are calculated for protostars and their environments using the hydrodynamic code STELLAR to describe the growing star itself. The code is modified with constant and variable accretion models with the inclusion of episodic bursts to produce stars of final masses of $1 - 100M_{\odot}$. Luminosity, radius, temperature and mass parameters are tracked throughout the stellar evolution to find potential signature features of each accretion model.

Indications as to why all accretion methods are supported by observation are found and methods of distinguishing between them are suggested. Recent ATLASGAL observations are used to investigate the appropriate methods of statistical comparison between observational and theoretical data. Progress is made toward successful comparisons of theoretical and observational data, and a method of Initial Mass Function analysis using clump mass and luminosity distribution data is suggested.

Acknowledgements

I am exceptionally grateful to Prof. Michael Smith, for providing excellent support, guidance and insight throughout this project.

I'd also like to thank the University of Kent for providing research facilities and materials required.

Thank you to H. Yorke for providing the modified STELLAR code and R. Kuiper for giving advice of its application.

A much needed thank you to my family and friends for support and encouragement.

Lastly I'd like to thank Charlotte, without whom this project would have been finished much sooner.

List of Figures

1.1	The modern understanding of the convective and radiative structures contained within stars. The low mass stars are fully convective which would comply with Emden's work. The greater masses have more complex systems involving both convective and radiative sectors.(Sun.org, 2016)	5
1.2	A collection of images of the Crab Nebula (NGC 1952) highlight the differences of what is shown in the different wavebands. The left column from top to bottom contains radio, visible and x-ray wavelengths. The right column from top to bottom contains infrared, ultraviolet and gamma ray wavelengths. Infrared spectra shows cooler star forming regions whilst Ultra violet show intense heat of main sequence stars. Note the radio image is a combination of two different radio wavebands combined. Credit to; NRAO, 2016b, NRAO, 2016a, NASA/JPL-Caltech/R. Gehrz (University of Minnesota), 2016, NASA, ESA, J. Hester and A. Loll (Arizona State University), 2016, NASA/Swift/E. Hoversten, PSU, 2016, NASA/CXC/SAO/F.Seward et al, 2016, NASA/DOE/Fermi LAT/R. Buehler, 2016	8
1.3	A false colour image of β Pictoris in the infrared band. The bright regions on opposite sides of the centroid show the remnants of an accretion disk around a young star. It is likely that the remaining disk will go on to form planets. Credit to Jean-Luc Beuzit, et al. Grenoble Observatory, European Southern Observatory, 2016	9

2.1	A heat map view of gas densities across the x-z plane of a 3D simulation (Kuiper 2011). The image comes from the model at 10kyr and $120M_{\odot}$ protostellar core. The protostellar region of high density can be seen at centered at the bottom of the figure.	18
2.2	A diagram of the first principles gas in a cylinder scenario. . .	19
2.3	The grid setup of the STELLAR as shown in Bodenheimer et al., 2006, the variables of density, nuclear energy, opacity and, total energy ($\rho, E_{nuc}, \kappa, \epsilon$ respectively) are all found as functions of the variables shown at the top of the grid. M_r is the lagrangian co-ordinate, with pressure, radius, temperature and, luminosity being the four dependent variables (P, r, T, L , respectively).	33
2.4	The evolutionary track for radius as a function of radius, as found by the CAPS code used in Smith, 2014. The figure shows an extreme example of the pre main sequence phases using a star with a final mass of $300M_{\odot}$. Labels on the figure, 1, 2, 3 and, 4 outlining the adiabatic accretion, swelling, KH contraction and main sequence transition phases, respectively.	35
3.1	The four different modelled accretion rates plotted as a function time for a star of $10M_{\odot}$	40
4.1	The radius tracks for protostars of final mass, $100M_{\odot}$. All four accretion methods are coloured accordingly as found in the legend.	56
4.2	The radius tracks for protostars of final mass, $50M_{\odot}$. All four accretion methods are coloured accordingly as found in the legend.	57
4.3	The radius tracks for protostars of final mass, $25M_{\odot}$	57
4.4	The radius tracks for protostars of final mass, $10M_{\odot}$	58
4.5	The radius tracks for protostars of final mass, $8M_{\odot}$	58
4.6	The radius tracks for protostars of final mass, $6M_{\odot}$	59
4.7	The radius tracks for protostars of final mass, $5M_{\odot}$	59
4.8	The radius tracks for protostars of final mass, $1M_{\odot}$	60

4.9	The H-R track for a star of $100M_{\odot}$ final mass using the cold constant accretion method. The dashed line represents the total luminosity and the solid coloured line represents the core luminosity.	61
4.10	The H-R track for a star of $10M_{\odot}$ final mass using the cold constant accretion method. The dashed line represents the total luminosity and the solid coloured line represents the core luminosity.	62
4.11	The H-R track for a star of $1M_{\odot}$ final mass using the cold constant accretion method. The dashed line represents the total luminosity and the solid coloured line represents the core luminosity.	62
4.12	The H-R track for a star of $100M_{\odot}$ final mass using the cold accelerated accretion method. The dashed line represents the total luminosity and the solid coloured line represents the core luminosity.	63
4.13	The H-R track for a star of $10M_{\odot}$ final mass using the cold accelerated accretion method. The dashed line represents the total luminosity and the solid coloured line represents the core luminosity.	64
4.14	The H-R track for a star of $1M_{\odot}$ final mass using the cold accelerated accretion method. The dashed line represents the total luminosity and the solid coloured line represents the core luminosity.	64
4.15	The H-R track for a star of $100M_{\odot}$ final mass using the cold exponential accretion method. The dashed line represents the total luminosity and the solid coloured line represents the core luminosity.	65
4.16	The H-R track for a star of $10M_{\odot}$ final mass using the cold exponential accretion method. The dashed line represents the total luminosity and the solid coloured line represents the core luminosity.	66

4.17 The H-R track for a star of $1M_{\odot}$ final mass using the cold exponential accretion method. The dashed line represents the total luminosity and the solid coloured line represents the core luminosity.	66
4.18 The H-R track for a star of $100M_{\odot}$ final mass using the cold power law accretion method. The dashed line represents the total luminosity and the solid coloured line represents the core luminosity.	67
4.19 The H-R track for a star of $10M_{\odot}$ final mass using the cold power law accretion method. The dashed line represents the total luminosity and the solid coloured line represents the core luminosity.	68
4.20 The H-R track for a star of $1M_{\odot}$ final mass using the cold power law accretion method. The dashed line represents the total luminosity and the solid coloured line represents the core luminosity.	68
4.21 The Mass Luminosity tracks using the cold constant accretion method. The final masses of the stars associated with tracks from left to right, $1M_{\odot}, 5M_{\odot}, 10M_{\odot}, 25M_{\odot}, 100M_{\odot}$. .	70
4.22 The Mass Luminosity tracks using the cold accelerated accretion method. The final masses of the stars associated with tracks from left to right, $1M_{\odot}, 5M_{\odot}, 10M_{\odot}, 25M_{\odot}, 100M_{\odot}$.	71
4.23 The Mass Luminosity tracks using the cold exponential accretion method. The final masses of the stars associated with tracks from left to right, $1M_{\odot}, 5M_{\odot}, 10M_{\odot}, 25M_{\odot}, 100M_{\odot}$.	72
4.24 The tracks for clump luminosity as a function of clump mass using the cold power law accretion method. The final masses of the stars associated with tracks from left to right, $1M_{\odot}, 5M_{\odot}, 10M_{\odot}, 25M_{\odot}, 100M_{\odot}$	73
4.25 Constant Distribution Results	75

4.25 The ATLASGAL distributions for MMB YSO and HII object types for the left, central and right column respectively. The dashed lines on plots A,B,C,D,E,F,G,H,I,J,K represent star of final masses 1, 2, 4, 5, 6, 8, 10, 15, 20, 25 and, $100M_{\odot}$ respectively, using the constant accretion method.	78
4.26 Accelerated Distribution Results	79
4.26 The ATLASGAL distributions for MMB YSO and HII object types for the left, central and right column respectively. The dashed lines on plots A,B,C,D,E,F,G,H,I,J,K represent star of final masses 1, 2, 4, 5, 6, 8, 10, 15, 20, 25 and, $100M_{\odot}$ respectively, through the exponential accretion.	82
4.27 Exponential Distribution Results	83
4.27 The ATLASGAL distributions for MMB YSO and HII object types for the left, central and right column respectively. The dashed lines on plots A,B,C,D,E,F,G,H,I,J,K represent star of final masses 1, 2, 4, 5, 6, 8, 10, 15, 20, 25 and, $100M_{\odot}$ respectively, through the exponential accretion method.	86
4.28 Power Law Distribution Results	87
4.28 The ATLASGAL distributions for MMB YSO and HII object types for the left, central and right column respectively. The dashed lines on plots A,B,C,D,E,F,G,H,I,J,K represent star of final masses 1, 2, 4, 5, 6, 8, 10, 15, 20, 25 and, $100M_{\odot}$ respectively, through the power law accretion method.	90
4.29 The accelerated accretion rate over time for both the smooth and burst accretion models. The final mass achieved is shown in the lower graph.	91
4.30 The radius as function of mass tracks for cold constant accretion with episodic bursts. The tracks stars of final masses $1M_{\odot}$, $5M_{\odot}$, $10M_{\odot}$ and, $20M_{\odot}$ respectively.	93
4.31 The radius as function of mass tracks for cold constant accretion with episodic bursts. The tracks of final masses $2M_{\odot}$, $4M_{\odot}$, $6M_{\odot}$ and, $8M_{\odot}$ respectively.	93

4.32 The radius as function of mass tracks for cold accelerated accretion with episodic bursts. The tracks represent stars of final masses $15M_{\odot}$, $10M_{\odot}$, $5M_{\odot}$ and, $1M_{\odot}$ respectively.	94
4.33 The radius as function of mass tracks for cold accelerated accretion with episodic bursts. The tracks represent stars of final masses $8M_{\odot}$, $6M_{\odot}$, $4M_{\odot}$ and, $2M_{\odot}$ respectively.	94
4.34 The radius as function of mass tracks for cold exponential accretion with episodic bursts. The tracks represent stars of final masses $20M_{\odot}$, $10M_{\odot}$, $5M_{\odot}$ and, $1M_{\odot}$ respectively.	95
4.35 The radius as function of mass tracks for cold exponential accretion with episodic bursts. The tracks represent stars of final masses $8M_{\odot}$, $6M_{\odot}$, $4M_{\odot}$ and, $2M_{\odot}$ respectively.	95
4.36 The radius as function of mass tracks for cold exponential accretion with episodic bursts. The tracks represent stars of final masses $20M_{\odot}$, $10M_{\odot}$, $5M_{\odot}$ and, $1M_{\odot}$ respectively.	96
4.37 The radius as function of mass tracks for cold exponential accretion with episodic bursts. The tracks represent stars of final masses $8M_{\odot}$, $6M_{\odot}$, $4M_{\odot}$ and, $2M_{\odot}$ respectively.	96
4.38 The H-R track for a star of $10M_{\odot}$ final mass using the cold constant accretion method with bursts. The dashed line represents the total luminosity and the solid coloured line represents the core luminosity.	97
4.39 The H-R track for a star of $1M_{\odot}$ final mass using the cold constant accretion method including bursts. The dashed line represents the total luminosity and the solid coloured line represents the core luminosity.	98
4.40 The H-R track for a star of $10M_{\odot}$ final mass using the cold accelerated accretion method including bursts. The dashed line represents the total luminosity and the solid coloured line represents the core luminosity.	98
4.41 The H-R track for a star of $1M_{\odot}$ final mass using the cold accelerated accretion method including bursts. The dashed line represents the total luminosity and the solid coloured line represents the core luminosity.	99

4.42 The H-R track for a star of $10M_{\odot}$ final mass using the cold exponential accretion method.	99
4.43 The H-R track for a star of $1M_{\odot}$ final mass using the cold exponential accretion method including bursts. The dashed line represents the total luminosity and the solid coloured line represents the core luminosity.	100
4.44 The H-R track for a star of $10M_{\odot}$ final mass using the cold power law accretion method including bursts. The dashed line represents the total luminosity and the solid coloured line represents the core luminosity.	100
4.45 The H-R track for a star of $1M_{\odot}$ final mass using the cold power law accretion method.	101
4.46 The Mass Luminosity tracks using the cold constant accretion method. The final masses of the stars associated with tracks from left to right, $1M_{\odot}, 5M_{\odot}, 10M_{\odot}, 20M_{\odot}$	102
4.47 The Mass Luminosity tracks using the cold accelerated accretion method. The final masses of the stars associated with tracks from left to right, $1M_{\odot}, 5M_{\odot}, 10M_{\odot}, 25M_{\odot}, 100M_{\odot}$. .	103
4.48 The Mass Luminosity tracks using the cold exponential accretion method. The final masses of the stars associated with tracks from left to right, $1M_{\odot}, 5M_{\odot}, 10M_{\odot}, 20M_{\odot}$	104
4.49 The tracks for clump luminosity as a function of clump mass using the cold power law accretion method. The final masses of the stars associated with tracks from left to right, $1M_{\odot}, 5M_{\odot}, 10M_{\odot}, 20M_{\odot}$	105
4.50 All Constant Burst Distribution Results	106
4.50 The ATLASGAL distributions for MMB YSO and HII object types for the left, central and right column respectively. The dashed lines on plots A,B,C,D,E,F,G,H,I represent star of final masses 1, 2, 4, 5, 6, 8, 10, 15 and, $20M_{\odot}$ respectively, using the constant accretion method including episodic bursts.	108
4.51 All Accelerated Burst Distribution Results	109

4.51	The ATLASGAL distributions for MMB YSO and HII object types for the left, central and right column respectively. The dashed lines on plots A,B,C,D,E,F,G,H represent star of final masses $1,2,4,5,6,8,10$ and $15M_{\odot}$ respectively, using the accelerated accretion method including episodic bursts.	111
4.52	All Exponential Burst Distribution Results	112
4.52	The ATLASGAL distributions for MMB YSO and HII object types for the left, central and right column respectively. The dashed lines on plots A,B,C,D,E,F,G,H,I represent star of final masses $1, 2, 4, 5, 6, 8, 10, 15$ and, $20M_{\odot}$ respectively, using the exponential accretion method including episodic bursts.	114
4.53	All Power law distribution results	115
4.53	The ATLASGAL distributions for MMB YSO and HII object types for the left, central and right column respectively. The dashed lines on plots A,B,C,D,E,F,G,H,I represent star of final masses $1, 2, 4, 5, 6, 8, 10, 15$ and, $20M_{\odot}$ respectively, using the power law accretion method including episodic bursts. .	117
5.1	The four different models and the accumulated mass as a function of time. From top to bottom, the plots show the results of stars of final masses $100M_{\odot}, 10M_{\odot}$ and $,1M_{\odot}$ respectively	120
5.2	The maximum peak radius achieved for each of the smooth accretion models at each modelled mass. Note the accelerated model $100M_{\odot}$ result is obscured by the constant data point.	122
5.3	Urquhart et al., 2014 ATLASGAL observational data. Luminosity and mass are given in solar units.	125
5.4	Frequency distribution of luminosity mass ratios from Urquhart et al., 2014 ATLASGAL data. L-M ratio is in solar units. . . .	126
5.5	Normalised frequency distribution of luminosity mass ratios from Urquhart et al., 2014 ATLASGAL data. Each object type was normalised against itself only.	127

5.6 This figure is taken from Calvet, Hartmann, and Strom, 2000. The accretion versus time graph displays potential ideas on the evolution of disk accretion and the different phases that occur. Early infall burst accretion, moving to a more irregular 'noisy' disk accretion.	130
5.7 An ideal scenario depicting the growth of a sphere of influence by a protostellar core in a cylindrical filament. The black dot serves as a central point for a protostar. The red lines represent the sphere of influence, with dashed line as potential future sphere. d is the diameter of cylinder, Δr is the change in radius, ΔL is the change in length.	131

Chapter 1

Introduction

Stars are the most fundamental objects in the universe, they provide host for planetary systems and other celestial objects. The energy they provide is the driving force to many natural phenomena including life. Massive stars provide the highly energetic radiation that drives the turbulence in clouds aiding low mass star formation. Low mass stars form in large numbers locking up the majority of mass in their local cluster. The evolutionary processes in which stars are formed is relatively well understood but there is still much left to be known. Observing the formation process is difficult due to the embedded nature of protostars and the long time scale over which it occurs. New observations like those from the Herschel Space Observatory are bettering the ability of imaging objects in optically thick clouds, however other methods are still required to achieve a complete understanding. A numerical model that is able to map stellar evolution from protostar to main sequence for all star masses, is the next logical step for better understanding the processes and consequences involved with star formation. We aim to do this by modelling the evolutionary tracks for a range of star masses via variable accretion models.

The fundamental basis for star formation is the gravitational collapse of a giant molecular cloud to form a protostellar core which further accumulates mass from the same cloud to eventually reach main sequence. There are many complexities involved in the process including radiation feedback and fragmentation.

Stellar astrophysics is a well documented field with many people working towards a general goal to better understand our place in the universe around us. As such, star formation holds a central position in astrophysical research.

- Gravitational collapse of molecular clouds to form a protostellar core.
- Protostellar core growth via circumstellar disk accretion due to conservation of angular momentum. As a consequence flow inversion due to radiation is avoided.
- Radiative feedback and magnetic fields have strong influence of star formation in the local cluster.
- The equations that govern the internal evolution of protostellar cores.

There remains a lot to be worked out and ideas that need further developing. Our research will aim to provide insight into some of the more problematic ideas.

- Star formation occurs in thick molecular clouds blocking or hindering observation. As such a complete detailed map of the formation process is not easily possible.
- The accretion rate is still largely debated.
- Spherically symmetric accretion is largely disregarded but the constant accretion rate it uses is still used widely in stellar modelling.
- Stars $> 10M_{\odot}$ are thought to accrue mass well into the main sequence but the ability to do this is not understood.
- It is unknown if the stellar accretion method of low mass stars is applicable to high mass stars formation.
- Recent works have pointed towards the inclusion of episodic accretion bursts, the effects and importance of which are not fully developed.
- It is uncertain if accretion rates conform to one model throughout the entire evolution or if there is a progressive change over the cycle. Recent works have purported a power law for low mass stars with high masses moving to an accelerated rate.

We aim to address some of these problems through the use of a complete core evolution hydrodynamic code. Adjusting key variables and compiling

the results to produce the evolutionary tracks for each model. We aim to be able to use the tracks and other data as guide to what is happening in the early star stages when they are still embedded in their local molecular cloud. We track the data of mass, luminosity and, temperatures throughout the entire evolution to then plot the model tracks. We then aim to compare the luminosity mass function to recent observational data from Urquhart et al., 2014. By the end of this paper, we aim to have determined the effectiveness of the modelling approach to solve a variety of astrophysical problems, if the accretion models we used are viable and, if the data produced can be used in aiding analysis of observations.

1.1 Star formation history

Star formation has been a point of serious debate in astrophysics for nearly two centuries now, with many different view points to try and understand the process. In the 1800's, the laws of thermodynamics were applied to the idea of infalling material to provide the energy of the sun. Lord Kelvin and Hermann von Helmholtz proposed that the sun's energy was sourced from the pool of matter shrinking as it cooled Helmholtz, 1856, they also realised the age of the sun could be estimated by comparing the gravitational potential energy to the luminosity. As such the Kelvin-Helmholtz timescale (eq. 2.108) was conceived, an equation that still holds great importance and an understanding of it is required later in our work.

The Kelvin idea for the energy source of the sun would not be refuted successfully for fifty years. Hindered by our lack of knowledge in other related fields, namely atomic physics. With the progress made in to the atomic structure it became known that under extreme gravitational conditions the electro-weak force could be overcome to combine atomic nuclei, resulting in a massive release of energy, this idea was gradually accepted as the prevailing theory with further evidence Aston, 1920. It was apparent that this energy was essential life support for stars by providing the energy to maintain high internal pressures to prevent star collapse.

The material state of stars had long been assumed as a liquid but in 1870

Homer Lane made the first calculations of stellar structure with the star being composed of a gas not liquid. His work aimed to determine surface temperature densities and pressure. Whilst not completely successful, it was the first observed result of when stars lose energy the subsequent contraction would lead to an increase in temperature not a decrease.

The early 1900's led to the first use of a polytropic model, where the pressure is dependent upon density. Robert Emden built upon previous work of a fully convective spherically symmetric perfect gas by including the idea of pressure density relation which would later become known as the Lane-Emden equation. Using the established equations of hydrostatic equilibrium and mass conservation (eq. 2.22 and eq. 2.24), a derivation for the density dependence upon the radius of star could be found. This relation was dependent upon the polytropic index, a function that is derived from the bulk modulus.

It wasn't until 1916 that the idea of radiation pressure playing a crucial role in the stellar equilibrium would be seen as viable. Arthur Eddington revisited the idea of radiation pressure as the major balancing force within stars and established many other principles associated. Eddington proposed that the temperature gradient is determined by the distribution of energy sources within the star and, the stellar opacity, which was evaluated by mostly electron scattering. Eddington established an upper limit of luminosity, at which point the radiation pressure would exceed the gravitational force resulting in rapid loss of stellar material. Eddington was working alongside Francis Aston when in 1920 he published a paper on highly accurate mass measurements of isotopes Aston, 1920. Aston found the individual masses of hydrogen atoms were greater than when combined into a helium atom, the deficit of mass was related to energy by the speed of light squared. This revolutionary finding allowed Eddington to reach a conclusion that the energy source within a star came from the combining of hydrogen into helium Eddington, 1920.

From the 1930's through to the 1950's further development in atomic and quantum physics would give way to new more complete understanding of main sequence evolution including the proton proton cycle and, the carbon nitrogen oxygen cycle. Both fusion cycles are crucial for comprehensive

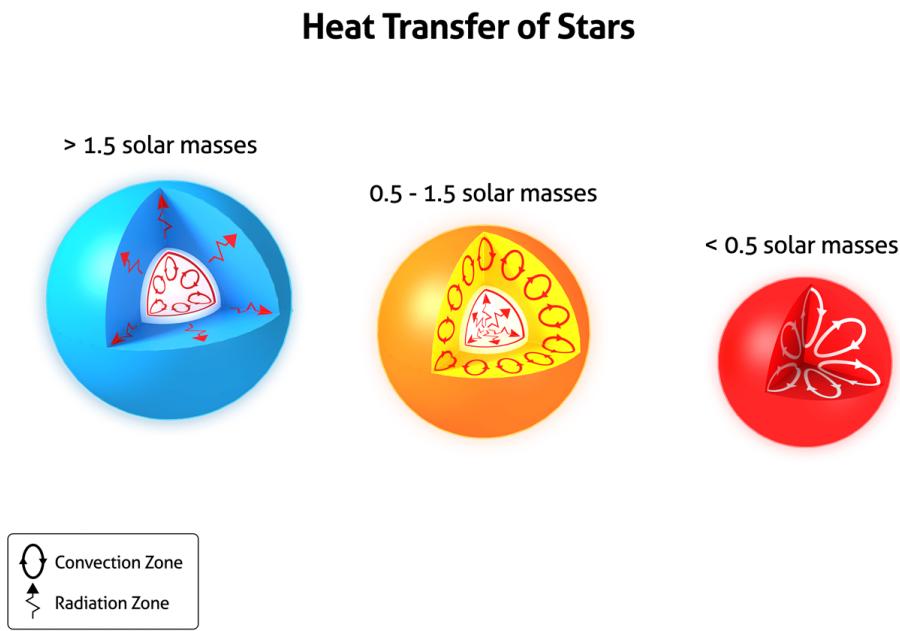

FIGURE 1.1: The modern understanding of the convective and radiative structures contained within stars. The low mass stars are fully convective which would comply with Emden's work. The greater masses have more complex systems involving both convective and radiative sectors.(Sun.org, 2016)

evolutionary models.

Subrahmanyan Chandrasekhar and Eddington both individually worked upon post main sequence astrophysics and extremely dense stars. Observation of a star in a binary system, now known as 40 Eridani, had shown a spectral type of a very hot white star but with a respectively low luminosity. This was the first discovery of a white dwarf star. Eddington stated that the observed density of the white dwarf was completely plausible. Chandrasekhar would eventually go on to derive the upper limit of white dwarf mass of which could be stable due to electron degeneracy pressure countering gravity Chandrasekhar, 1931.

By this point in time the majority of the main sequence cycle, from birth to death, was known but not understood. The 1950's gave way to electromagnetic astronomy. Radio, X-ray, Gamma ray, ultra violet and infrared telescopes were all now feasible for astrophysical observations. This progression allowed us to probe deeper and further into the universe than ever before. Star forming regions of dark molecular clouds were now accessible

and soon became known as the nurseries of which stars are born. Previously never seen before star clusters were now observed deep within their local cloud.

Long term evolution of star formation calculations were labourious and largely impractical before the advent of computers. Mentioned by Martin Schwarzschild ([Schwarzchild, 1962](#),[Longair, 2013](#))

"A person can perform more than twenty integration steps per day...so that for a typical single integration of, say, forty steps, less than two days is needed."

The 1960's would give astrophysicists access to the computation power needed to run simulations. Conversion from mathematical integrations to a computational compatible methods were required. During this time period Louis G. Henyey produced an automatic solution finder for stellar evolution equations now known as the Henyey method [Bodenheimer et al., 2006](#), a numerical method that is used within the main code of this paper.

Modern simulation and modelling approaches to star formation are still crucial to astrophysical understanding. Protostars are naturally much colder than their main sequence counterpart and are still embedded within their molecular cloud which hides signature evidence of the star. The time spent in the protostellar and pre main sequence are very short in comparison to the full life cycle so proportionally, protostars are much fewer in observation to main sequence stars. Even with modern space telescopes for all wavebands, finding and defining protostars is still very difficult. Modelling can help fill this void of knowledge by converting principle mechanisms and materials into a simulated space time environment. Modelling also has the advantage that the entire process is mapped from beginning to end, giving a visualisation of the full cycle not just a snapshot as is found with observation.

Later in chapter [2](#), a quantitative evaluation is given of the accepted principle physics which is used in astrophysics and this paper. Here however, we summarise the process for introductory purposes.

Giant molecular clouds contain thousands to several million solar masses of

material, of which is balanced in an equilibrium of gas pressure, kinetic energy and gravity. An isolated system could exist almost perpetually. However, radiative losses will reduce the energy contained within over time, combined with turbulent winds the equilibrium is destabilised and collapse occurs. This is referred to as triggered formation. The mass requirement for star formation is known as the jeans mass.

A collapsing region will continue towards a protostellar stage if the gravitational potential energy is successfully displaced through radiative losses. A central region will become the protostellar core when its opacity increases to a point where its internal energy cannot be removed. Further collapse of outer gaseous regions only increase the core temperature through shocks. Once reaching around $2000K$, the hydrogen and helium will become fully ionised and the hydrogen molecules will dissociate. Infalling matter will coalesce into a circumstellar disk through which matter will accrete onto the star. This disk allows for bipolar outflows in which the energy can be dissipated, this reduces the radiation pressure on the disk and angular momentum of the disk, allowing for accretion to continue.

Once the temperature is increased sufficiently, deuterium fusion begins. This process maintains internal core temperatures and allows the continuation of mass accretion before the hydrogen burning stages can begin, at which point the star would be considered main sequence. Beyond this is the post main sequence phase and the end of life paths that will be taken depending upon star mass, these stages are beyond the aims of this paper which just focuses on protostellar to main sequence.

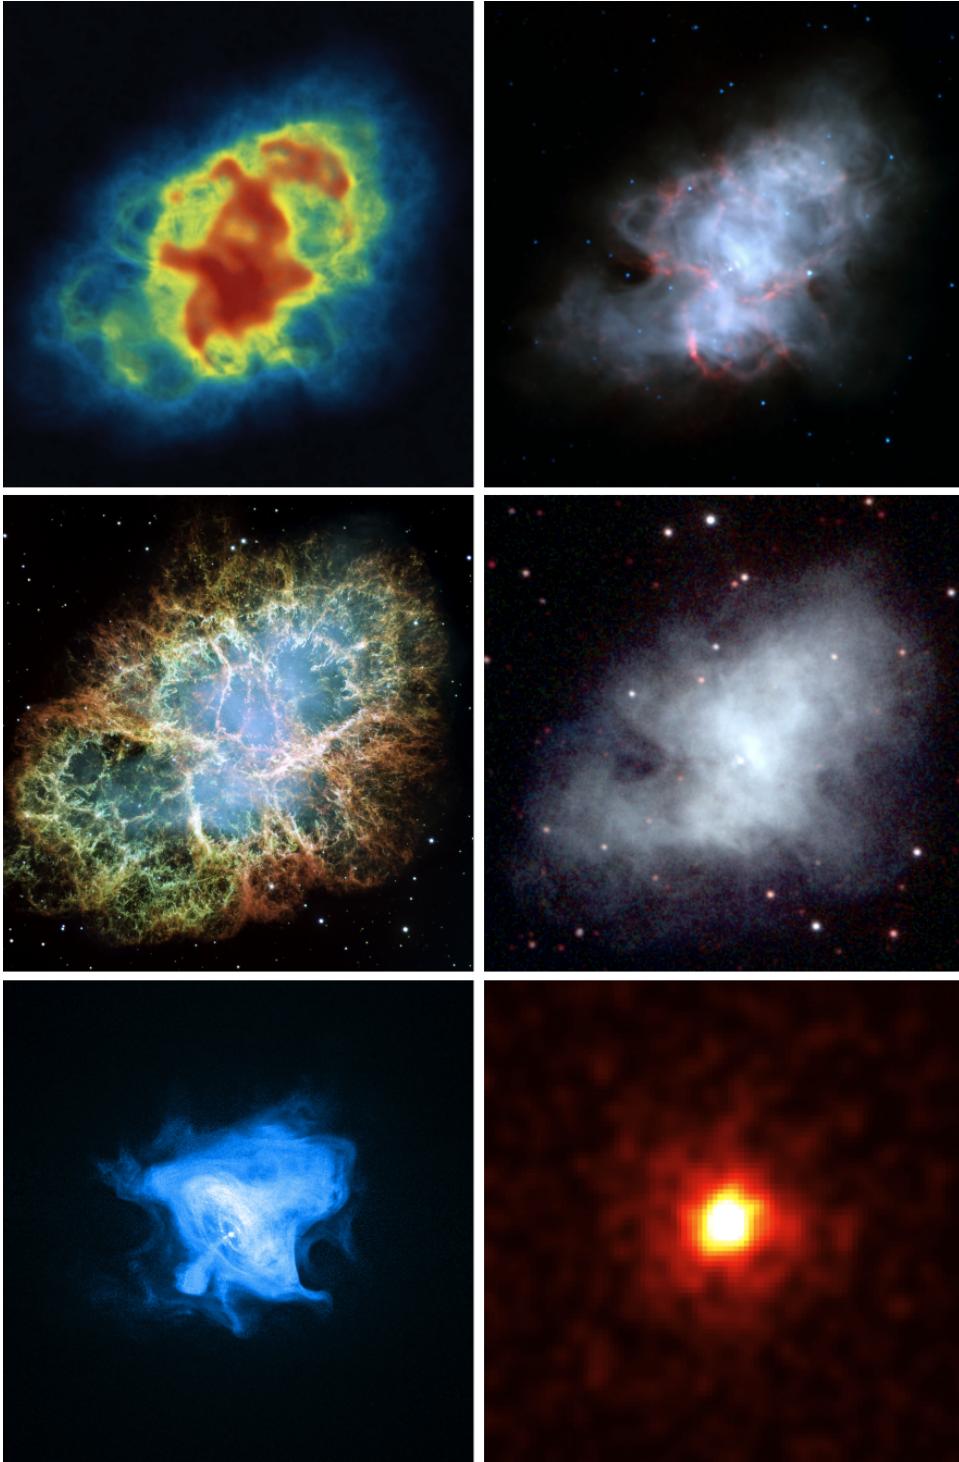

FIGURE 1.2: A collection of images of the Crab Nebula (NGC 1952) highlight the differences of what is shown in the different wavebands. The left column from top to bottom contains radio, visible and x-ray wavelengths. The right column from top to bottom contains infrared, ultra-violet and gamma ray wavelengths. Infrared spectra shows cooler star forming regions whilst Ultra violet show intense heat of main sequence stars. Note the radio image is a combination of two different radio wavebands combined.

It is likely that the remaining disk will go on to form planets. Credit to Jean-Luc Beuzit, et al. Grenoble Observatory, European Southern Observatory, 2016

Chapter 2

Method Theory

This section will lead through the majority of background knowledge required to understand the early pre-main sequence evolution of stars and the hydrodynamic code used in this research project. Starting with the well understood theoretical physics and evolutionary mechanics, then moving to how this translates into a computational simulation.

2.1 Jeans Criterion

The first stage to star formation requires a molecular cloud, a region of diffuse gas and dust with enough mass where a star can begin to form. The criteria required for collapse into a proto star is defined by the Jeans Mass. Assuming a spherical cloud, a portion of the cloud can be determined to collapse if the local gravitational force is greater than the pressure from within. Assuming a spherical cloud of uniform density, the gravitational potential energy of the cloud can be approximated as

$$U \sim -\frac{3}{5} \frac{GM_c^2}{R_c} \quad (2.1)$$

Where M_c and R_c are the mass and radius of the cloud, respectively. From virial theorem, a gravitationally balanced system can be shown as stable by

$$2K + U = 0 \quad (2.2)$$

where K is kinetic energy. A cloud's internal kinetic energy can be approximated as

$$K = \frac{3}{2} Nkt \quad (2.3)$$

Where N is the number of particles, which we can also define using

$$N = \frac{M_c}{\mu m_H} \quad (2.4)$$

Where μ is the average molecular weight. From 2.2 we can see that gravitational collapse will occur when $2K < |U|$, and then substituting what we just defined

$$\frac{3}{2} \frac{M_c k t}{\mu m_H} < \frac{3}{5} \frac{G M_c^2}{R_c} \quad (2.5)$$

We can define the radius of a cloud assuming initial density of ρ_0 , to replace the mass of the system.

$$R_c = \left(\frac{3M_c}{4\pi\rho_0} \right)^{1/3} \quad (2.6)$$

Now we can substitute this into 2.5 to find the Jeans mass.

$$M_J \simeq \left(\frac{5kT}{G\mu m_H} \right)^{3/2} \left(\frac{3}{4\pi\rho_0} \right)^{1/2} \quad (2.7)$$

It should be noted, this derivation works under the assumption that the entirety of the cloud is collapsing. If however, the spherical section of mass is embedded within a GMC it will be subject to an external pressure which will reduce the mass required. Known as the Bonner-Ebert mass it is given as

$$M_{BE} = \frac{c_{BE} v_T^4}{\rho_0^{1/2} G^{3/2}} \quad (2.8)$$

Where

$$v_T = \sqrt{kT/\mu m_H} \quad (2.9)$$

is the speed of sound in the isothermal material. The c_{BE} is a dimensionless constant of $\simeq 1.18$

We can also use the definitions of timescales to determine if a cloud will collapse or expand. The time scale of expansion driven by radiation

$$t_s \simeq \frac{R}{c_s} \propto \frac{R \rho^{\frac{1}{2}}}{P^{\frac{1}{2}}} \propto m^{\frac{1}{3}} \rho^{-\frac{1}{3}} T^{-\frac{1}{2}} \quad (2.10)$$

Where R is radius of the cloud. c_s is the speed of sound in the material. ρ is the density of the cloud. T is the temperature. P is pressure and m is mass.

The timescale of free fall collapse is given as:

$$t_{ff} \simeq \left(\frac{Gm}{r^3} \right)^{-\frac{1}{2}} \propto (G\rho)^{-\frac{1}{2}} \quad (2.11)$$

Where G is the gravitational constant.

As such a star can be shown to collapse if $t_{ff} \ll t_s$.

More recent work has shown that the Jeans criteria whilst classically correct, is not the main mechanism of collapse. GMCs do not exist in a calm motionless state, energy input from local clusters will cause turbulent motion within the clouds. The turbulence will cause confined dense regions which then exceed the Jeans criteria. So whilst the Jeans criteria is applicable to some extent, the turbulence induced changes happen on timescales much shorter than if the cloud were only subject to the free fall collapse. As such it is much more likely that turbulence is the initial cause of collapse which is then taken over by gravity.

2.1.1 Fragmentation

Once a cloud has exceeded the Jeans criteria and has begun to collapse, a process of fragmentation takes place. Fragmentation is problematic in understanding massive star formation. It would follow that, a massive star forms from a cloud in which its mass is many times the final mass of the star. However as a molecular cloud collapses its density increases, which leads to portions of the cloud exceeding the Jeans criteria, the cloud then begins to fragment into multiple collapsing regions. The size of these fragmenting regions can be found by

$$\frac{d^2r}{dt^2} = \frac{Gm(r)}{r^2} - \frac{1}{\rho} \frac{\partial \rho}{\partial r} = \frac{-Gm}{r^2} - 4\pi r^2 \frac{\partial \rho}{\partial m} \quad (2.12)$$

Fragmentation starvation (Girichidis et al., 2011) is a common outcome in hydrodynamic simulations where stars can't accumulate enough material to reach higher masses, however this was not explored in this research. The process of fragmentation will continue until either radiation feedback increases the temperature, and thus internal pressure, enough to prevent collapse. The other method of fragmentation suppression is through magnetic field interactions.

As clouds collapse the temperature increases, as shown later (1.26), this energy is released through radiation. Whilst the clouds are optically thin this radiation is largely unobstructed and allows for the core to collapse further. Once the cloud becomes optically thick the radiation is mostly contained preventing energy release, this increases the gas pressure which counters the gravitational force preventing further collapse of the cloud. This process, known as radiation feedback, works best in the central regions of a collapsing molecular cloud up to $\simeq 1000AU$. Due to the Jeans mass requirement being dependent on $T^{3/2}$, even a moderate increase in temperature increases the mass requirement by factors of $\simeq 10$ and thus slowing or stopping fragmentation. Magnetic fields work in two ways to prevent fragmentation. Firstly, a collapsing cloud needs to preserve angular momentum, doing so by rotating faster around the centroid as it moves closer to that point. However, with the presence of magnetic field lines threaded throughout the cloud, the faster rotation in the inner rings, cause the field lines to become twisted. This twisted field generates a tension force, moving angular momentum from inner regions to the outer. Commonly known as magnetic braking, the result aids the collapse process drastically. The second effect of magnetic fields is similar to radiative feedback, in that the mass of the cloud must overcome magnetic flux pressure. Whilst many regions in clouds have a supercritical mass able to overcome the magnetic flux, it still provides a preventative force which shown in simulations to prevent fragmentation by factors of ≈ 2 , Krumholz, 2014

2.2 Stellar Equilibrium

The equilibrium of a star is reached when gravitational force is balanced by the internal pressure. We can use these balanced equations at all stages of the stars life from protostar to main sequence to determine its current state. The gravitational force upon a small mass located at distance r from centre of spherically symmetric sphere:

$$F_{Grav} = \frac{-GM_r\Delta m}{r^2} \quad (2.13)$$

Where M_r is the interior mass, inside a sphere of radius r . Pressure being:

$$P \equiv \frac{F}{A} \quad (2.14)$$

Where F is force, and A is area. If we consider first a cylindrical system of; length r , mass dm and, circular face of area A , at distance from a star. The differential of force across the cylinder is

$$dF_{Pres} = VdP \quad (2.15)$$

By using Newton's second law we can now define the total force present with change in radius over time.

$$dm\ddot{r} = F_g - dF_{Pres} = -\frac{GM_r dm}{r^2} - AdP \quad (2.16)$$

Replacing the differential mass element with density.

$$dm = \rho A dr \quad (2.17)$$

Substituting into 2.16 and dividing by the volume.

$$\rho\ddot{r} = -\frac{GM_r\rho}{r^2} - \frac{dP}{dr} \quad (2.18)$$

This is the time dependent relation of the described scenario, substituting for spherical geometry we get

$$\ddot{r} = -\frac{Gm}{r^2} - \frac{\partial P}{\partial r} \frac{1}{\rho} \quad (2.19)$$

and considering the relation

$$dr = \frac{dm}{4\pi r^2 \rho} \quad (2.20)$$

we can get the spherical time dependent relation of forces over the sphere.

$$\ddot{r} = -\frac{Gm}{r^2} - 4\pi r^2 \frac{\partial P}{\partial m} \quad (2.21)$$

Once the star is in a state of equilibrium, i.e. no longer time dependent we can finally see the forces balanced using

$$\frac{dP}{dm} = -\frac{Gm}{4\pi r^4} \quad (2.22)$$

It must be noted that there must exist a pressure gradient throughout the sphere or protostar to counter gravity.

2.3 Mass Conservation

Considering a spherically symmetric star with a thin shell of mass dM_r and thickness dr , located at distance r . The volume of shell can be approximated to be

$$dV = \rho(4\pi r^2 dr) \quad (2.23)$$

and as such we can derive the mass conservation equation.

$$\frac{dM_r}{dr} = 4\pi r^2 \rho \quad (2.24)$$

This mass conservation shows the mass distribution must vary with distance from the centre of the stellar body.

2.4 Upper Mass Limit

There are several problems that outline a hard limit to the mass a star can reach through accretion, these problems include stellar winds and ionisation feedback, we will focus on two of the more directly influential problems to our model. The first being fragmentation already discussed and the second being radiation feedback. The radiation problem arises from the equilibrium of mass to radiation pressure, and that at some point the internal energy and therefore radiation pressure, will be greater than the gravitational force. We can find this limit by equating the inward force of gravity 2.13 and the outward force of luminosity, defined as

$$F_{rad} = \frac{\kappa L}{4\pi r^2 c} \quad (2.25)$$

where κ is the opacity constant. Gravitational force can be shown as dominant only if

$$\frac{L}{M} < \frac{4\pi Gc}{\kappa} = 2500 \left(\frac{\kappa}{5cm^2g^{-1}} \right)^{-1} \frac{L_\odot}{M_\odot} \quad (2.26)$$

From observations we know that proto stars exceeding $\sim 20M_\odot$ have luminosities greater than $2500L_\odot$. As such, it would stand that a protostar exceeding $20M_\odot$ would generate radiation pressure great enough to blow away and starve itself of all further mass. The first understanding to how stars continue to accrete mass lies in the assumption of spherical nature and uniform radiation from the protostars surface on to the surrounding cloud. An upper mass limit of $\sim 40M_\odot$ is found in spherically symmetric simulation (Hosokawa & Omukai 2009). We know from observation that this $\sim 40M_\odot$ upper limit is not found in reality and that stars much more massive are able to form. A different mechanism of formation must exist.

We know that molecular clouds will hold a non-zero angular momentum value as such, when matter falls inwards toward the protostellar core the conservation of angular momentum must be held, and thus results in the accreting matter to form into a flattened accretion disk along the axis of net angular momentum. This also allows for 'beamed' radiation to be emitted from opposing polar regions, perpendicular to the flattened disc. As such, the polar radiation force over a significant solid angle will far exceed the gravitational force, creating radiation driven cavities. The result is radiation is emitted away from the axis of the accretion disk and the gravitational force along the disk axis is then great enough to overcome radiation pressure and continues accreting mass onto the protostar. New simulations such as 2.1 show strong agreement with this idea (Krumholz et al., 2009, Kuiper et al., 2011).

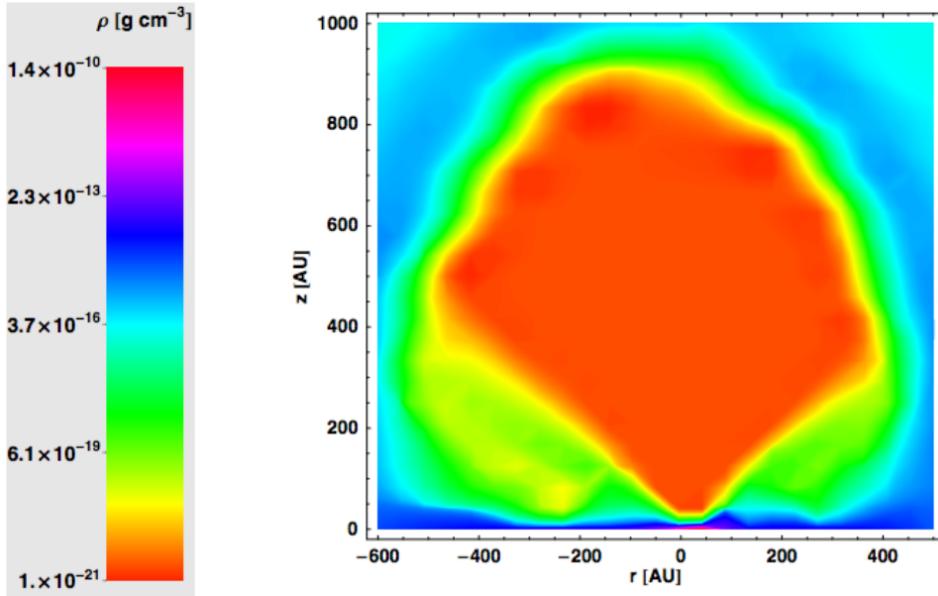

FIGURE 2.1: A heat map view of gas densities across the x-z plane of a 3D simulation (Kuiper 2011). The image comes from the model at 10kyr and $120M_{\odot}$ protostellar core. The protostellar region of high density can be seen at centered at the bottom of the figure.

2.5 Pressure

To fully understand previous equations outlined (1.23,1.25) we must determine the pressure of the cloud system as an equation of state. The total pressure within a star comes from several sources including radiation, gas pressure and degeneracy pressure, the derivations of which will be outlined below. Derivations using methods from Carroll and Ostlie, 2006

The ideal gas law

$$PV = nkT \quad (2.27)$$

is an equation of state which will be used to help determine the other pressure relations involved in the star system. where k is the Boltzmann constant and N is number of particles in the system.

2.5.1 Pressure Integral

Taking a cylinder of length Δx and cross sectional area A , containing a gas of point like particles all of mass m , 2.2. The gas is assumed to behave like an ideal gas, i.e. interacts via perfectly elastic collisions. The gas incident to the walls of the container will change momentum entirely along the normal

axis. Using Newtons second and third law

$$f = ma = \frac{dp}{dt} \quad J = \int_{\Delta t} f dt = \Delta p \quad (2.28)$$

Where J is impulse. From our scenario we can determine that the impulse imparted on the wall is the negative of the change in momentum experienced by the particle.

$$f \Delta t = -\Delta p = 2p_x \hat{i} \quad (2.29)$$

The gas will travel twice the length of the container before hitting the wall again. The time between these intervals is then defined

$$\Delta t = 2 \frac{2x}{v_x} \quad (2.30)$$

Where v_x is the velocity along the x axis. The speed scalar of the particle will remain constant due to the perfect elastic collisions. The average force

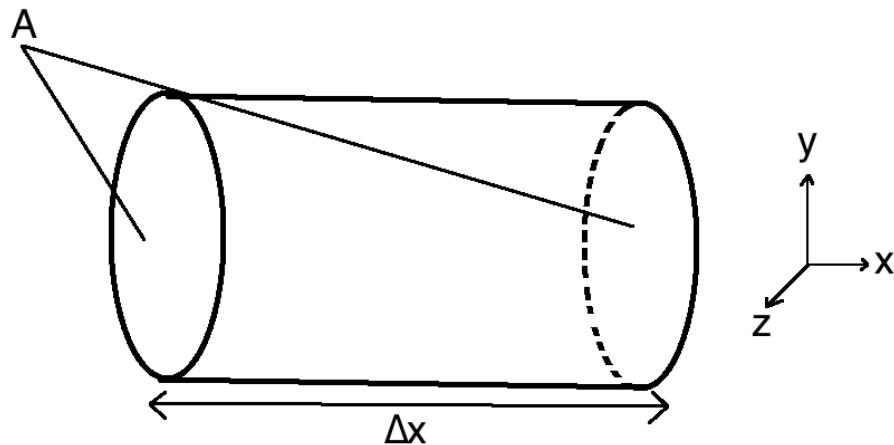

FIGURE 2.2: A diagram of the first principles gas in a cylinder scenario.

exerted by a particle is then given

$$f = \frac{2p_x}{\Delta t} = \frac{p_x v_x}{\Delta x} \quad (2.31)$$

Given the velocity vector is

$$v^2 = v_x^2 + v_y^2 + v_z^2 \quad (2.32)$$

and for a system containing a large number of particles it can be assumed

$$\bar{v}_x^2 = \bar{v}_y^2 = \bar{v}_z^2 = \frac{v^2}{3} \quad (2.33)$$

As such the average force per particle is

$$f(p) = \frac{1}{3} \frac{pv}{\Delta x} \quad (2.34)$$

The particles in the cylinder will have a range of momenta between p and $p + dp$ and we can then define the number of particles with this momenta as $N_p dp$. Then the total number of particles in the box is given

$$N = \int_0^\infty N_p dp \quad (2.35)$$

with the total force of these particles given

$$dF(p) = f(p)N_p dp = \frac{1}{3} \frac{N_p}{\Delta x} p v d p \quad (2.36)$$

Integrating over all momentum

$$F = \frac{1}{3} \int_0^\infty \frac{N_p}{\Delta x} p v d p \quad (2.37)$$

Noting that the Volume of the cylinder is the area of the cross section multiplied by the length, $\Delta V = A\Delta x$.

$$n_p dp \equiv \frac{N_p}{\Delta V} dp \quad (2.38)$$

so the pressure exerted on the wall of the cylinder is

$$P = \frac{1}{3} \int_0^\infty n_p p v d p \quad (2.39)$$

So we have arrived at the pressure relation to the number density of particles in the system. This equation will work for massless and massive particles. Going further we will evaluate the equation for an ideal gas in terms of the average molecular weight.

2.5.2 Ideal Gas Pressure

In the case where the gas is non-relativistic we can equate momentum to mass multiplied by velocity, $p = mv$. Which we can substitute into 2.39

$$P = \frac{1}{3} \int_0^\infty mn_v v^2 dv \quad (2.40)$$

Where $n_v dv$ has replaced $n_p dp$ and now represents the number of particles in the gas with speeds between v and $v + dv$. In an ideal gas we can use the Maxwell-Boltzmann velocity distribution as the function $n_v dv$.

$$n_v dv = n \left(\frac{m}{2\pi kT} \right)^{\frac{3}{2}} e^{-mv^2/2kT} 4\pi v^2 dv \quad (2.41)$$

where $n = \int_0^\infty n_v dv$. When 2.41 is substituted back into the pressure integral 2.39 and after simplification we get

$$P_g = nkT \quad (2.42)$$

the number of particles can be replaced by taking the density of the gas and dividing by the average mass of particles in the system.

$$P_g = \frac{\rho kT}{\bar{m}} \quad (2.43)$$

Where \bar{m} is average mass of the particles in the gas. We can now define this mean molecular weight average in terms of hydrogen atom masses.

$$\mu = \frac{\bar{m}}{m_H} \quad (2.44)$$

which we can now use to define the ideal gas pressure relation in terms of molecular weights.

$$P_g = \frac{\rho kT}{\bar{m}} \quad (2.45)$$

To go further and simplify the definition of the equation, we can define the average molecular weight in relation to hydrogen masses.

$$\mu \equiv \frac{\bar{m}}{m_H} \quad (2.46)$$

where m_H is mass of hydrogen atom. As such

$$P_g = \frac{\rho k T}{\mu m_H} \quad (2.47)$$

we have now arrived at the final relation of gas pressure to average molecular weight. This average molecular weight is more complex for star systems as the gases contain a large mix of elements and in various ionisation states which all contribute to differing average weight. The ionisation plays a part as the free electron gas must also be considered. The two final equations for average molecular weight of a neutral and a fully ionised gas can be stated respectively as

$$\frac{1}{\mu_n} \simeq X + \frac{1}{4}Y + \left\langle \frac{1}{A} \right\rangle_n Z \quad (2.48)$$

and

$$\frac{1}{\mu_i} \simeq 2X + \frac{3}{4}Y + \left\langle \frac{1+z}{A} \right\rangle_i Z \quad (2.49)$$

where X is the fraction of Hydrogen, Y is the fraction of Helium, and Z is the fraction of heavier elements. $\left\langle \frac{1}{A} \right\rangle_n$ is the averaged weight of the heavier elements. For young stars the typical values of X, Y and Z are $\approx 0.70, 0.28, 0.02$ respectively, which correspond to values of, $\mu_n = 1.30$ and $\mu_i = 0.62$.

2.5.3 Radiation Pressure

Radiation emitted will generate a pressure due to the momentum imparted by photons in absorption or reflections. The momentum held by a photon is defined

$$p_\gamma = \frac{hv}{c} \quad (2.50)$$

Where h is the Planck constant, v is the frequency of the photon, c is the speed of light. Going back to the fundamental pressure integral equation 2.39, we can substitute the photon value of momentum, noting that the interchangeable relation that $n_p dp = n_v dv$.

$$P_{rad} = \frac{1}{3} \int_0^\infty h v n_v dv \quad (2.51)$$

We can go further by noting that $nvdv$ is the number density of photons with frequencies in the range from v to $v + dv$. By then multiplying by the energy of each photon over that frequency range, we get energy density.

$$P_{rad} = \frac{1}{3} \int_0^\infty u_v dv \quad (2.52)$$

If we then substitute the energy density, $u_v dv$, for the Planck blackbody radiation distribution and integrating we can resolve to

$$P_{rad} = \frac{1}{3} a T^4 \quad (2.53)$$

where the radiation constant $a \simeq 7.566 \times 10^{-16} J m^{-3} K^{-4}$. This is our final expression of pressure driven by radiation from a blackbody of $T > 0K$.

2.5.4 Degeneracy Pressure

So far the pressures defined have been described using classical physics, however we must account for the quantum mechanical contributions within the system. It can be seen from eq2.27, that as $T \rightarrow 0, V \rightarrow 0$. We know however, that particles will have to occupy a non-zero volume even if temperature is ~ 0 . As such, at a point where the gas particles occupy a small volume with low energies (corresponding to the low temperatures), they will break the Pauli exclusion principle. To avoid this the particles must hold a higher momentum than classical physics would dictate.

The maximum energy of an electron in a completely degenerate gas at $T = 0K$, is given by the Fermi energy, ϵ_F . This maximum energy is determined by a 3d wave in a box scenario and using the de Broglie wavelength momentum relation. Assuming box of length L on each side contains an electron represented by a standing wave function. The wavelength of the electrons can be stated as

$$\lambda_x = \frac{2L}{N_x} \quad \lambda_y = \frac{2L}{N_y} \quad \lambda_z = \frac{2L}{N_z} \quad (2.54)$$

Where $N_{x/y/z}$ is the integer quantum number associated with the respective

axis dimension. Using the de Broglie relation we can define these wavelengths as momenta

$$p_x = \frac{hN_x}{2L}, \quad p_y = \frac{hN_y}{2L}, \quad p_z = \frac{hN_z}{2L} \quad (2.55)$$

So the total energy of a particle is written

$$\epsilon = \frac{p^2}{2m} \quad (2.56)$$

where $p^2 = p_x^2 + p_y^2 + p_z^2$ and as such total energy in this model is

$$\epsilon = \frac{\hbar^2}{8mL^2}(N_x^2 + N_y^2 + N_z^2) = \frac{\hbar^2 N^2}{8mL^2} \quad (2.57)$$

Each electron can hold a spin value of $\pm 1/2$ and as such the total of unique quantum numbers N_x, N_y, N_z , is equal to two times the total number of electrons in the gas. Assuming a large enough sample of electron, which a protostellar system would definitely have, the space occupied would be out to a radius of $N = \sqrt{N_x^2 + N_y^2 + N_z^2}$ for positive N -space values. This evaluates the total number of electrons within a given space.

$$n_e = 2\left(\frac{1}{8}\right)\left(\frac{4}{3}\pi N^3\right) \quad (2.58)$$

Rewriting in terms of N

$$N = \left(\frac{3n_e}{\pi}\right)^{\frac{1}{3}} \quad (2.59)$$

Substituting into equation 2.57 we can determine the Fermi energy.

$$\epsilon_F = \frac{\hbar^2}{2m_e}(3\pi^2 n_e)^{\frac{2}{3}} \quad (2.60)$$

where m_e is the mass of an electron and n_e is the number of electrons within the volume of the system, $n_e = N_e/L^3$. Now with the definition of Fermi energy we can use it to determine the degeneracy pressure. We make the assumption that the condition for degeneracy has been met, which is stated as

$$\frac{T}{\rho^{2/3}} < \mathcal{D} \quad (2.61)$$

With degeneracy being greater for smaller values of $T/\rho^{2/3}$. To find the

pressure due to degeneracy we must combine the Pauli exclusion principle and the Heisenberg uncertainty principle. Using equation 2.39 and making the assumption that momentum of each electron is equal, it becomes

$$P \approx \frac{1}{3} n_e p v \quad (2.62)$$

with n_e being electron number density. In a completely degenerate gas the separation between electrons is $\sim n_e^{-1/3}$, as such the uncertainty of position cannot be larger than their physical separation, so $\Delta x \approx n_e^{-1/3}$. So now we can calculate the momentum in one axis as

$$p_x \approx \Delta p_x \approx \frac{\hbar}{\Delta x} \approx \hbar n_e^{1/3} \quad (2.63)$$

We can also assume that momentum in each of the three axes is equally likely and therefore we can assume the same value. From equipartition theorem we can say that

$$p^2 = p_x^2 + p_y^2 + p_z^2 = 3p_x^2, \quad p = \sqrt{3}p_x \quad (2.64)$$

We can now define the momentum using the number density of electrons that are fully ionised.

$$p \approx \sqrt{3}\hbar n_e^{1/3} \quad (2.65)$$

For non-relativistic speeds we know $v = \frac{p}{m_e}$ and as such

$$v \approx \frac{\sqrt{3}\hbar}{m_e} n_e^{1/3} \quad (2.66)$$

As such we can now substitute equations 2.66 2.63 into the new pressure integral, equation 2.62, resulting in the degeneracy pressure.

$$P = \frac{(3\pi^2)^{2/3}}{5} \frac{\hbar}{m_e} n_e^{5/3} \quad (2.67)$$

and then by evaluating the electron number density in terms of the ratio between protons and nucleons in the system we can find the degeneracy

pressure for our protostar.

$$P = \frac{(3\pi^2)^{2/3}}{5} \frac{\hbar}{m_e} \left[\left(\frac{Z}{A} \right) \frac{\rho}{m_H} \right]^{5/3} \quad (2.68)$$

The electron degeneracy pressure during early stages of the star formation contributes a small but not insignificant portion of total pressure. It must be noted that this is the non-relativistic case, the relativistic case again takes more effect in later stages of the star cycle where energy is much higher. It must also be noted that the neutron degeneracy pressure and the Chandrasekhar limit is not considered, as it only becomes significant in the later stages of a main sequence star when the main fusion cycles fuel has been consumed, a stage far beyond the early tracks we are researching.

2.6 Virial Theorem

Virial theorem is used to determine the relation between gravitational and internal energy.

$$V \frac{dP}{dm} = -\frac{1}{3} \frac{Gm}{r} \quad (2.69)$$

$$VdP = d(PV) - PdV = d(PV) - \frac{P}{\rho} dm = -\frac{1}{3} \frac{Gmdm}{r} \quad (2.70)$$

$$\int_{\text{centre}}^{\text{surface}} d(PV) = 0 \quad (2.71)$$

$V=0$ at the centre and $P(M)=0$ at the surface.

$$-3 \int_0^M \frac{P}{\rho} dm = - \int_0^M \frac{Gmdm}{r} = \Omega \quad (2.72)$$

Where Ω is the total gravitational potential energy. Using this theorem and applying it to an ideal gas with particles of mass m_g the temperature relation to the total internal energy.

$$P = \left(\frac{\rho}{m_g} \right) kT \quad (2.73)$$

In the described situation, the total internal energy at this phase of the stellar cycle is just the total kinetic energy of the particles.

$$U = \frac{3}{2} \frac{kT}{m_g} = \frac{3}{2} \frac{P}{\rho} \quad (2.74)$$

Substituting 2.74 and 2.72.

$$U = -\frac{\Omega}{2} \quad (2.75)$$

and also

$$U = \int_0^M \frac{3}{2} \frac{kT}{m_g} dm = \frac{3}{2} \frac{k}{m_g} \int_0^M T dm = \frac{3}{2} \frac{k\bar{T}M}{m_g} \quad (2.76)$$

Where \bar{T} is the average temperature, being defined as

$$\bar{T} = \frac{1}{M} \int_0^M T dm \quad (2.77)$$

As such the average temperature is related to the gravitational potential energy by

$$\bar{T} = \frac{2m_g U}{3kM} = -\frac{m_g \Omega}{3kM} \quad (2.78)$$

A stars gravitational energy can be written as $\Omega = -\alpha GM^2/R$ where α is a constant of how the mass is distributed in the star. As such from ref(1.23) gives

$$\bar{T} = \frac{\alpha m_g GM}{3kR} \quad (2.79)$$

Fundamentally stars heat up as they contract and cool as they expand. Re-writing 2.79, with the radius as the function of average density, $\bar{\rho} = 3M/4\pi R^3$, to give

$$\bar{T} = \frac{\alpha m_g G}{3k} \left(\frac{4\pi}{3}\right)^{1/3} M^{2/3} \bar{\rho}^{-1/3} \quad (2.80)$$

2.7 Luminosity

The luminosity of the star is determined by considering the energy generated by stellar material. If we consider an infinitesimal mass the defined contribution to luminosity is

$$dL = \epsilon dm \quad (2.81)$$

where ϵ is the total energy contribution per second per kilogram of mass, $\epsilon = \epsilon_{gravity} + \epsilon_{nuclear}$. The early evolution energy contribution is all gravity until deuterium burning begins. For a spherically symmetric star the mass of a thin shell of thickness

$$dr = dM_r = \rho dV = 4\pi r^2 \rho dr \quad (2.82)$$

dividing by the thickness of the shell, the luminosity is given as a differential

$$\frac{dL_r}{dr} = 4\pi r^2 \rho \epsilon \quad (2.83)$$

This gives the luminosity due to all mass within the interior of the shell that has radius r . We can also determine luminosity from temperature using the Stephan-Boltzmann law

$$P = 4\pi\sigma T^4 \quad (2.84)$$

Where σ is the Stephan-Boltzmann constant. P is the total power emitted from an object over its surface given it emits like a black-body. Assuming spherical geometry we can relate the luminosity to this power by

$$L = 4\pi R^2 \sigma T^4 \quad (2.85)$$

As such the luminosity can be determined from the temperature of the star. The luminosity of a protostar is hard to evaluate in reality, due to the molecular cloud surrounding the star being optically thick, blocking the majority of radiation escaping.

2.8 Energy Transport Mechanisms

The three standard energy transport mechanisms, radiation convection and conduction are all present in stars. Conductive transport however is mostly insignificant to the total energy movement. Both radiation and convective mechanisms will be outlined here.

Radiation transfers energy from gravitation and nuclear reactions via photons. The photons are emitted, absorbed and, re-emitted in almost random directions. This radiation travel is clearly conditional to the opacity of

the material. If we consider a radiation pressure gradient

$$\frac{dP_{rad}}{dr} = \frac{\bar{\kappa}\rho}{c} F_{rad} \quad (2.86)$$

Where κ is the opacity of the material. We can also describe the radiation pressure as

$$\frac{dP_{rad}}{dr} = \frac{4}{3}aT^3 \frac{dT}{dr} \quad (2.87)$$

equating the two

$$\frac{dT}{dr} = \frac{-3}{4ac} \frac{\bar{\kappa}\rho}{T^3} F_{rad} \quad (2.88)$$

substituting the force due to radiation with the luminosity relation

$$F_{rad} = \frac{L_r}{4\pi r^2} \quad (2.89)$$

The result for radiation transport is

$$\frac{dT}{dr} = -\frac{3}{4ac} \frac{\bar{\kappa}\rho}{T^3} \frac{L_r}{4\pi r^2} \quad (2.90)$$

The convection of matter is due to the more energetic buoyant mass moving towards the surface of the star and the cooler mass sinking to the centre. We can describe the rising mass as an adiabatically moving bubble which after travelling a distance will then give up its energy to the surroundings by dissolving into it. We can describe this bubble first by differentiating the ideal gas equation 2.47

$$\frac{dP}{dr} = -\frac{P}{\mu} \frac{d\mu}{dr} + \frac{P}{\rho} \frac{d\rho}{dr} + \frac{P}{T} \frac{dT}{dr} \quad (2.91)$$

Using the relation of $V \equiv 1/\rho$, the adiabatic relation between pressure and density is

$$P = K\rho^\gamma \quad (2.92)$$

differentiating with respect to the radial distance

$$\frac{dP}{dr} = \gamma \frac{P}{\rho} \frac{d\rho}{dr} \quad (2.93)$$

If we assume that μ is a constant, then 2.91 and 2.93 can be combined to give the adiabatic temperature gradient.

$$\frac{dT}{dr} \Big|_{ad} = -\left(1 - \frac{1}{\gamma}\right) \frac{\mu m_H}{k} \frac{GM_r}{r^2} \quad (2.94)$$

2.9 Stellar Equations

We have now arrived at the end of the principle mechanisms and the associated equations that describe stellar evolution. These methods can be used throughout the entire evolution from cloud through to main sequence to end of life. These equations cannot be solved analytically and need adjustment for numerical modelling. By replacing differentials with difference equations, this places numerical limits to the equations allowing them to be evaluated completely. In most numerical simulations, these limits would be implemented by incremental radial distances allowing evaluation of pressure, temperature, luminosity and, mass across these spherical shells. However the model in this research has similar principles but uses grid based limits as will be outlined later.

2.10 Boundary Conditions

At the centre of stars where $M_r = 0$ and where $L_r = 0$, singularities will develop at the centre when using the equations previously defined. As such, the usual solution is to expand a first order taylor series with the boundary condition at a small value of M_r near the centre, where

$$r = \left(\frac{3}{4\pi\rho_c}\right) M_r^{1/3} \quad (2.95)$$

$$P = P_c - \frac{1}{2} \left(\frac{4\pi}{3}\right)^{1/3} G \rho_c^{4/3} M_r^{2/3} \quad (2.96)$$

$$L_r = \left(E_{nuc} - \frac{d\epsilon}{dt} - P \frac{dV}{dt}\right)_c M_r \quad (2.97)$$

$$T = T_c - \frac{1}{2} \left(\frac{4\pi}{3}\right)^{1/3} G \left(\frac{\rho_c^{4/3}}{P_c} \text{cdot} \nabla_c \cdot T_c \cdot M_r^{2/3}\right) \quad (2.98)$$

The gradient is set dependent upon if the layer is radiative or convective. The Luminosity Mass function goes to a constant but must be evaluated off centre. Density, temperature and, pressure are all calculated.

Using 2.85 the boundary condition for the surface of the star can be determined. Where in this case the luminosity would be the value from the surface and R is the radius to the surface. If we assume a fixed gravitational acceleration, the atmospheric hydrostatic equilibrium can be found

$$\frac{dP}{dr} = -\frac{GM_r\rho}{r^2} = -g\rho \quad (2.99)$$

with the optical depth being defined $d\tau = -\kappa_R\rho dr$ and assuming $M = M_r$ in the atmosphere

$$\frac{dP}{dr} = \frac{g}{\kappa_R} \quad (2.100)$$

By integrating between the limits of τ being small at the surface inwards to a value of $2/3$ to define the photosphere as

$$\kappa_{ph}P_{ph} = \frac{2}{3}g \quad (2.101)$$

As such the end equation is an approximation for the two boundary conditions of the surface of the star. More detailed models of the atmospheric composition are desired to be able to make better comparisons with observation. The hydrogen and helium elements tend to have different levels of ionisation, dependent on their location within the star. Inner layer hydrogen and helium is mostly fully ionised, whereas outer layers have only partial ionisation.

2.11 The Model

We use the provided program, STELLAR, that comes alongside the textbook of Bodenheimer et al., 2006 with some adaptations. The STELLAR package is a hydrodynamic adaptive grid code that solves the stellar structure via the Henyey method.

The Henyey method solves implicitly and simultaneously the outlined equations at time, $t^{n+1} = t^n + \Delta t$. This has requirement for a initial resolved function at t^n . As with other interpolation techniques, once resolved the

found values are used to update the model variables including the composition χ , which will then be used in the next iterative step. STELLAR used a grid of mesh points, J , with $j = 1$ and $j = J$ as the centre of the star and surface of the star respectively. The surface also has defined $M_j = 0$, where $M_j = M$ where M is total mass. Incremental masses, $dM_j = M_j - M_{j-1}$ must be stored to avoid the subtraction of nearly equal quantities between grid points. The code will adapt the grid mesh to increase or decrease the numbers of mesh points for regions of rapid change, this is set up so the difference between M_j and M_{j+1} is no more than 3 – 4%. As a star develops, the pressure difference between the centre and the surface will increase greatly, as such the number of zones will need to be increased as t increases. The three principle equations previously outlined, eq2.20, eq2.22, eq2.97 and the diffusion approximation for all types of energy transport

$$\frac{dT}{dM_r} = -\frac{GM_r T}{4\pi r^4 P} \nabla \quad (2.102)$$

The radius r_j and the luminosity L_r are defined on the edges of the grid points, M_j . The pressure, density and temperature P_j, ρ_j, T_j are all defined as halfway between grid points such that the mass co-ordinate for them is $M_{j-1/2}$. As such the equations used in the code are redefined as

$$P_{j+1} - P_j + \frac{(M_{j+1/2} - M_{j-1/2})GM_j}{4\pi r_j^4} = 0 \quad (2.103)$$

$$r_j^3 - r_{j-1}^3 - (M_j - M_{j-1}) \cdot \frac{3}{4\pi \rho_j} = 0 \quad (2.104)$$

$$L_j - L_{j-1} - (M_j - M_{j-1}) \left[E_{nuc,j} - \frac{c_{P,j}(T_j - T_j^n)}{\Delta t} + \frac{\delta}{\rho_j} \frac{(P_j - P_j^n)}{\Delta t} \right] = 0 \quad (2.105)$$

$$T_{j+1} - T_j + \frac{(M_{j+1/2} - M_{j-1/2})GM_j}{4\pi r_j^4} \frac{B_{j+1} + B_j}{2} = 0 \quad (2.106)$$

Where $B = T_j \nabla_j / P_j$.

STELLAR requires initial values for variables at t^n point, as such a converged model of a protostellar core of approximately 50 jupiter masses, $0.05M_\odot$, luminosity of $2.2 \times 10^{-2}L_\odot$ and radius $0.56R_\odot$ was used at the centre of the grid.

The STELLAR code has been further developed to use an input file to

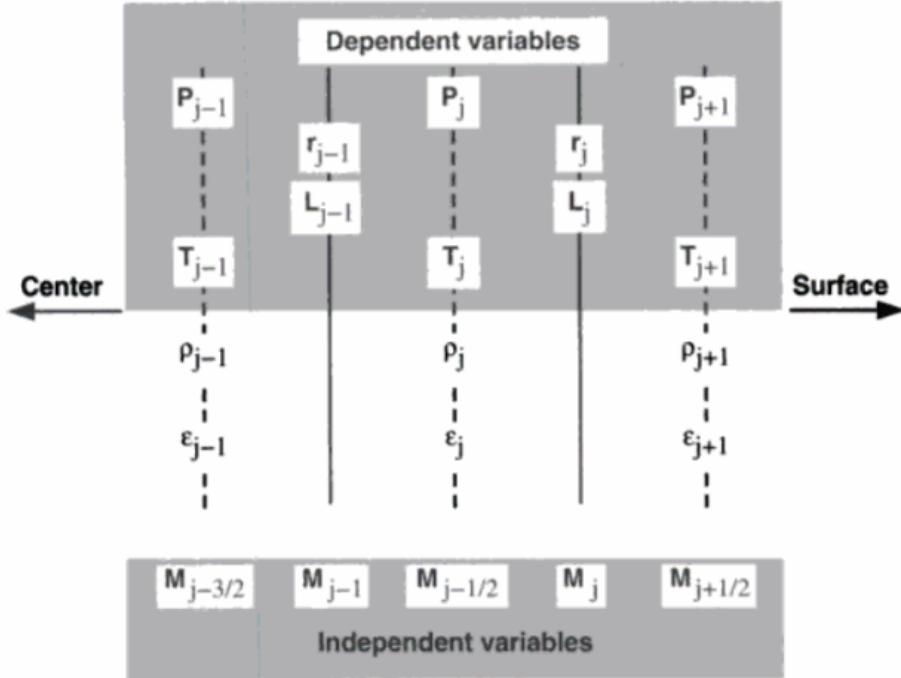

FIGURE 2.3: The grid setup of the STELLAR as shown in Bodenheimer et al., 2006, the variables of density, nuclear energy, opacity and, total energy ($\rho, E_{nuc}, \kappa, \epsilon$ respectively) are all found as functions of the variables shown at the top of the grid. M_r is the lagrangian co-ordinate, with pressure, radius, temperature and, luminosity being the four dependent variables (P, r, T, L , respectively).

predefine the mass accretion rate, time step and total time, externally to the STELLAR evolution method. Minor adjustment to the internal time step of STELLAR was made to scale. The early stages and through to the main accretion phase require greater accuracy, and thus a smaller internal time step, by adding a multiplicative factor of the current time to the fixed time step. This has small impact in early stages but increases the time step later which reduces total run time.

$$DTMIN = 1.0 \times 10^4 + (1.0 \times 10^{-5} \times TIMOD) \quad (2.107)$$

Where DTMIN is the minimum timestep and TIMOD is the internal current time of the program. This proved effective in reducing program run time with a change from ≈ 150 hours to $\approx 6 - 24$ hours. We made small additions to a makefile in order to reset certain files to an original state. These

files are altered when the program is run, which will cause program failure if they are reused from this altered state. The solution was to include a copy function that overwrites the altered file with the original, each time the program is compiled.

The main body of code has been designed to read in variables from a variety of input files. These variables allow control over internal functions, an example being the time step limits for the Henyey method. Assigning the variables in external files makes for a much simpler process in controlling how the program performs. We focused on developing one of these external files, ‘dummymain.f’. This file controls multiple fundamental variables, namely the mass flux and time frame of formation. We aimed to modify this file to specify variable or constant accretion models, with options to choose final mass and then inclusion of episodic bursts.

2.12 Pre Main Sequence Phases

A giant molecular cloud (GMC from here on in) contains large quantities of mass, on the order of millions of solar masses. These GMC’s will either expand or collapse depending on the Jeans instability criteria shown in 2.3. A collapsing cloud is decreasing in volume and as such, increasing its density. This increase allows for fragmentation to take place. Fragmentation is a series of localised collapsing envelopes within the GMC. This fragmentation process will lead to the generation of multiple protostellar cores. We focus on the processes after this fragmentation has taken place, by looking at one protostellar core and its encapsulating envelope.

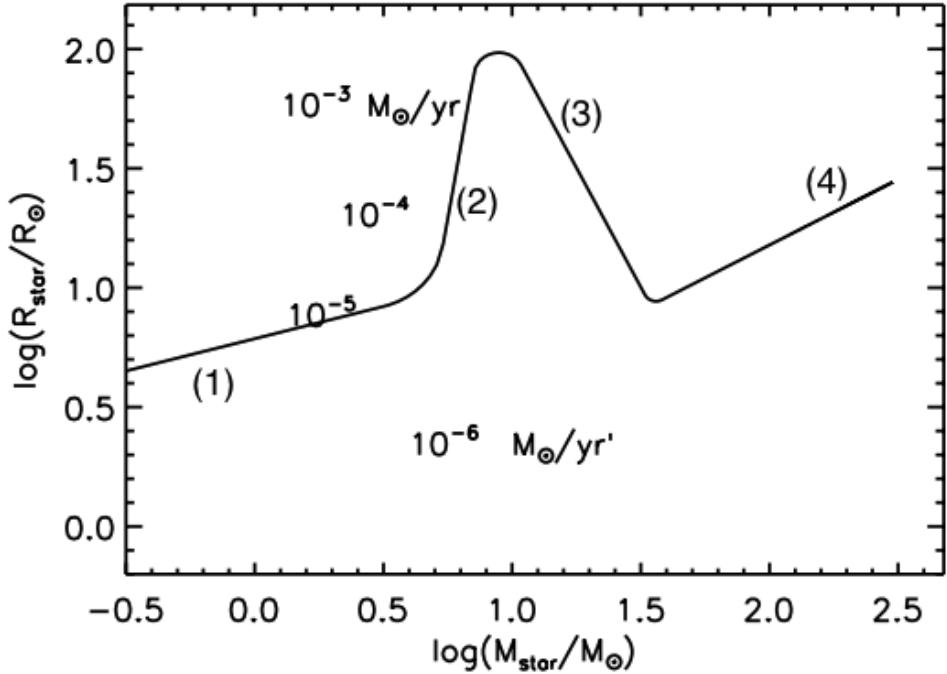

FIGURE 2.4: The evolutionary track for radius as a function of radius, as found by the CAPS code used in Smith, 2014. The figure shows an extreme example of the pre main sequence phases using a star with a final mass of $300M_{\odot}$. Labels on the figure, 1, 2, 3 and, 4 outlining the adiabatic accretion, swelling, KH contraction and main sequence transition phases, respectively.

2.12.1 Adiabatic Accretion

The central protostellar core will accrete mass from its surrounding envelope as it continues to collapse. This process of collapse leads to the increase of local density which corresponds to an increase in opacity. At some critical point during this stage, the opacity will have increased to a point where all the internal energy converted from potential energy will be absorbed and contained within the star itself. Since the energy is not lost from the system, we call this adiabatic collapse. The accretion of matter in this stage directly corresponds to an increase in temperature.

2.12.2 Swelling

The protostar will go through a swelling (interchangeably called bloating) phase if it reaches or exceeds an accretion rate of $\dot{M} \sim 10^{-5} M_{\odot}/\text{yr}$ as shown by Palla & Stahler (1990 & 1991). This process will happen before reaching

the zero age main sequence. The swelling occurs due to the internal temperatures of $\sim 10^6 K$ which initialises deuterium burning in the shell. This deuterium burning stage is crucial, stars more massive than $\sim 3M_\odot$ would not exist without the deuterium burning. The burning initiates convection within the core thus regulating internal temperature to keep below the hydrogen fusion temperature which allows the star to continue accreting mass. A scenario where the accretion exceeds $\dot{M} \sim 10^{-3} M_\odot/yr$ however, will go through the swelling phase regardless to the effect of deuterium burning. This swelling occurs due to the entropy contained in the deep centre of the star rapidly moving toward the outer shells and surface.

2.12.3 Kelvin-Helmholtz Contraction

The previous swelling phase will contribute to a decrease in opacity, the reversed method of reaching the adiabatic phase, as such the proto star becomes much more luminous allowing the energy from within to be radiated away. The Kelvin-Helmholtz timescale is given by

$$t_{kh} = \frac{\text{Total Energy}}{\text{Rate of energy Loss}} = \frac{GM^2}{RL} \quad (2.108)$$

A critical point will be reached whereby the timescale for radiating energy away, t_{KH} will be shorter than the accretion timescale, t_{acc} , allowing the total energy and therefore temperature to decrease. To maintain virial equilibrium, the star will contract. This contraction increases internal core temperature will lead to the eventual ‘ignition’ of the star, however this is not immediate and can take a significant time to happen, notably for low mass stars.

2.12.4 Main Sequence Transition

The transition from contraction to main sequence is a mass dependent time frame, massive stars will take somewhere in the same order as accretion time of $1 - 10 \times 10^5 yrs$ whereas low mass stars can take on the order of $10^6 - 10^8 yrs$. Over this time the temperature increases within the stellar core to a value $\geq 10^7$ where it is now great enough that Hydrogen fusion

can take place. This is the point at which we now define the protostellar core as a zero age main sequence star.

Chapter 3

Method

We aim to find connection between the results of our variable accretion rate model to previous work and observational data, with the eventual desire of being able to accurately produce a fully comprehensive stellar evolution for stars of all masses. A key step is determining a complete accretion method that holds true for all star formation within GMCs. Eventually equipping a three dimensional magneto-hydrodynamic code with a conclusive accretion model will lead to better understanding of star formation from cloud to main sequence.

Using the STELLAR code provided by Bodenheimer et al., 2006 we build on the ideas developed in Smith, 2014 aiming to produce more detailed tracks involving relations between mass, time, radius, temperature and luminosity. We also aim to model short episodic accretion bursts in line with the recent results from Hosokawa et al., 2016.

An interface to the STELLAR evolution code allowed the accretion rate and the different phases timescale to be defined externally. The accretion methods from Smith, 2014 were transcribed into the interface which then evaluates the accretion rate for each time step before being passed into the STELLAR evolution program.

3.1 Accretion

We explore four debated methods of protostellar accretion rates; constant, accelerated, a power law, and an exponential. We split the process into two defined stages of accretion; an initial main accretion phase set as the first $t_{acc} = 1 \times 10^5$ year period, this transitions into a minimum accretion period of 9×10^5 years which we call the clean up phase where accretion rate is set

to a minimum value of $\approx 10^{-7}M_{\odot}$. The clean up accretion stage is crucial to allow time for the evolution to evaluate fully. The incorporated minimum accretion rate keeps the program from collapsing early from breaking boundary conditions but the nominal accretion rate has small impact on the end result. This clean up accretion rate adds $\approx 1 - 2\%$ mass of the mass at the end of the first stage.

In the case of the power law and exponential, the accretion rate continues to drop throughout the entire run unless dropping below a $10^{-8}\frac{M_{\odot}}{yr}$ threshold rate, if passing this rate the program will fix it at the threshold rate until finishing all iterations. We still define it as the main accretion phase because 75% – 85% of the final mass is reached in the $10^5 yr$ time frame.

The total time for the evolution is $t_t = 10^6$ years, which we set the program to divide into 3×10^4 iterations at $1.052^9 s = 33.3$ years each.

For simplicity the accretion rate is calculated from a pre-defined value for the desired final mass of the star, allowing just one integer variable to be changed to achieve this. The calculations for accretion rate will be outlined further but note we include an efficiency factor of 0.7 as we assume a 30% loss of mass in jets from the protostar, Shu et al., 1994.

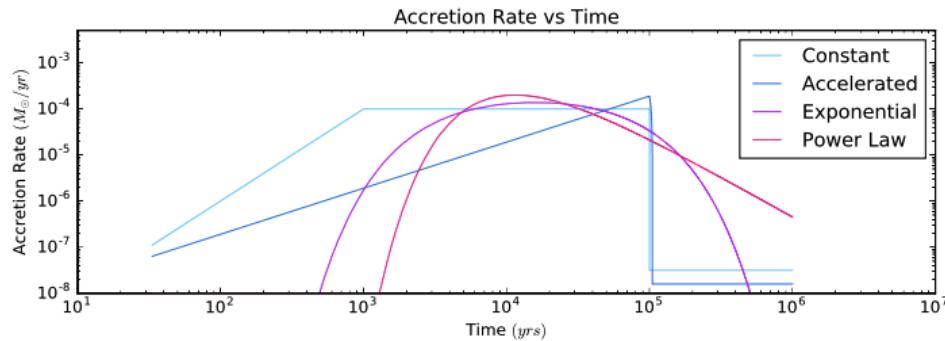

FIGURE 3.1: The four different modelled accretion rates plotted as a function time for a star of $10M_{\odot}$.

Shown in the figure 3.1 is the smooth accretion process for each method in which a $10M_{\odot}$ star was produced. Note the initial gradual increase to reach the main accretion phase rate for the constant method, used for stability. The clean up phase minimal accretion rates can be seen implemented after the $t = 10^5 yr$ point by the sharp drop to the minimum accretion rate. Note the differences between the exponential and power law accretion

methods; the exponential rapidly increases in rate earlier but not peaking as high. The power law rate begins to drop off sooner after reaching its peak but levels off the declining rate, whereas the exponential doesn't.

3.1.1 Constant

The constant accretion rate, a simple fixed rate generally used in isothermal sphere models Shu, 1977. Differing from Shu, 1977, our model has a finite limit of molecular gas. As such we model an accretion rate that holds steady until the end of the main accretion time where we assume the rate drops to a minimum as the molecular cloud resources are exhausted. The initial rate is determined by the total mass of the envelope and the speed of sound in the envelope.

The constant accretion rate coded is defined by the final mass desired

$$\dot{M}_{const} = \frac{M_f}{t_{acc}} \quad (3.1)$$

Where M_f is the final mass and t_{acc} is the time of the main accretion phase. We also include an efficiency of accretion later, due to the losses from jets and outflows. The program is susceptible to failure if large rapid changes occur such as the first iteration. To minimise this effect a small 1000 year stage at the beginning of the program is used, where the accretion is gradually increased to match the main accretion rate as defined by 3.1 and seen in figure 3.1.

3.1.2 Accelerated

An accelerated accretion is generally used for low to intermediate mass stars as it aids in solving the luminosity problem of protostellar cores, Offner and McKee, 2011. Determined by the increase in mass flux as a function of time followed by a steep drop off as the envelope's resources are depleted.

An accelerated accretion rate defines the mass accumulation as a proportional function of time as shown by McKee and Tan, 2003.

$$\dot{M}_* \propto t \quad (3.2)$$

The proportion derives from a protostellar sphere of influence growing as its mass increases, as such increasing the surrounding sphere of molecular gas that becomes gravitationally bound toward the core.

The definition coded for this accretion model is given using an initial accretion rate

$$\dot{M}_0 = \frac{M_\odot}{a} \times M_f \times \frac{2.857}{t_{acc}} \quad (3.3)$$

Where $\frac{M_\odot}{a}$ is the unit of solar masses per year. M_f is the final mass of the star given in solar masses. t_{acc} is the time of the main accretion phase in years. The factor of 2.857 is for inclusion of mass losses at 70% efficiency. As such the total mass accreted is given by:

$$\sum_{t=0}^{100,000} \dot{M}_t = M_0 \times t \times \frac{t_t}{t_{acc}} \quad (3.4)$$

Where t is the time. t_t is the total time (1×10^6 yrs).

3.1.3 Exponential

An exponential accretion model, Myers et al., 1998, is the optimal adaption of an accretion where infall is similar to the constant rate used with isothermal spheres but followed by a declining rate. This is given by

$$\dot{M}(t) = \frac{M_0}{t_f} e^{-t/\tau_f} \quad (3.5)$$

This rate is proportional to the mass loss rate of the envelope, but going further to model a rising period rather than starting at a high rate.

$$\dot{M}(t) = \dot{M}_0 e^{(2\tau_r/\tau_f)^{1/2}} e^{-\tau_r/\tau_f} e^{-t/\tau_f} \quad (3.6)$$

Where $\tau_f = t_{acc}/t_t$ and $\tau_r = \tau_f/10$. This generates the maximum accretion rate at time, $t_m = \sqrt{\tau_r \tau_f}$. For our model this peak time occurs at $t_m \approx 1.58 \times 10^4$ yrs.

3.1.4 Power Law

Calvet, Hartmann, and Strom, 1999 Shows strong observation support for an accretion with strong decay phase. As such we incorporate a power law drop off model as an accretion rate. Power law accretion is generally the preferred method for low-intermediate mass stars, Smith, Mac Low, and Heitsch, 2000.

The power law accretion rate is given:

$$\dot{M}_{power} = \dot{M}_0 \left(\frac{e}{\alpha}\right)^\alpha \left(\frac{t}{t_{acc}}\right)^{-\alpha} e^{-t_{acc}/t} \quad (3.7)$$

Where α is a constant that corresponds to the accretion rate curvature. 0.5 being a gradual accretion and 2-3 being an abrupt accretion.

The peak accretion rate in a power law model is early in the accretion phase and a sharp initial increase in mass flux rate. The early stage \ddot{M} is greater than the exponential model but starting around $\sim 10^3$ yrs later. The power law reaches its maximum \dot{M} before the other variable rate mechanisms and achieves at a greater peak value for \dot{M} .

3.1.5 Accretion Bursts

We attempt to model episodic accretion shocks, which we just refer to as bursts from here on in. It's shown that the majority of mass accreted doesn't come in the form of a steady progression but instead in massive accretion shocks of high intensity over a short time period. It has been shown that bursts are key to the fragmentation within the accretion disk which aids the formation of multiple star systems and planetary objects Stamatellos, Hubber, and Whitworth, 2011. The bursts are modelled to accrete 90% of the final stellar mass through the short $\approx 10^3$ yr burst phases with the final 10% accumulating in the 'off' state lasting 9×10^3 .

To couple the modelled accretion methods and a burst counter part, we pass the original calculation of accretion through a secondary modulo function which determines if the accretion will be in an on or off state. The modulo functions used to determine accretion state are coded as such

$$\text{IF} \left(\frac{i}{30} \bmod 10 \right) \neq 9 \text{ THEN } \dot{M} = \dot{M}_{min} \quad (3.8)$$

and

$$\text{IF}\left(\frac{i}{30} \bmod 10\right) = 9 \text{ THEN } \dot{M} = \dot{M}_{max} \quad (3.9)$$

where i is the current iteration of the program, $M_{min} = \dot{M} \times 0.111$ and, $M_{max} = \dot{M} \times 9.099$. Where the \dot{M} has already been calculated for its respective accretion method at that time point.

3.1.6 Input File

We make adjustments to an input file which calls the main STELCOR code. This file was originally put together by H.W, Yorke and can be seen used in Kuiper and Yorke, 2013. We made major alterations to the file to include the accretion models outlined and other front end adjustments. For fluidity in use, we include a series of requests informing the user to specify final mass, accretion time and which accretion model to use. Having all the models contained in one file and then being able to adjust the variables once executed greatly reduces a complete program run time.

The code contains all four accretion models with bursts. It can be seen that there is some deviation from the equations outlined to the ones used in the code for each model. There is some limitation with the Fortran code when it comes to more complex functions such as those found in the power law code and exponential models. An example, on lines 113 and 177, the included multiplicative factors of 2.86143×10^5 and 1.9804×10^5 are found using the capsule code Smith, 2014, as we cannot include solutions to partial gamma functions and integrations with this version of Fortran. The constant section has been commented fully to aid the user. The other three models use most of the same variables so are not commented on but differences in them can be followed by the equations outlined earlier. Not shown in the code above, but in the final dummymain.f file we include further choices for the episodic bursts.

3.2 Evolutionary Tracks

3.2.1 Mass Radius

We aim to provide a detailed map of the growth of stars through the pre main sequence phases providing insight into how the stellar evolution and structure effects the radius of the protostar. Radii of stars is a key observational quantity and as such mapping it as a function of stellar mass gives crucial understanding to the evolutionary stage a protostar is in.

3.2.2 Theoretical Hertzsprung Russell Track

Using our model and stellar equations (2.99 2.98) outlined earlier we can map the tracks of $\log(L/L_\odot)$ against $\log(T/T_\odot)$ for the pre-main sequence stars, sometimes referred to as the theoretical Hertzsprung Russell diagram. The tracks produced are governed by the chosen time frame and the values of internal parameters such as metallicity and opacity. These tracks provide use in determining age of stars and star clusters. These tracks whilst similar are not completely comparable to the Hertzsprung Russell diagrams comparing colour to temperature as the conversion from colour to luminosity is not a simple calculation and has multiple dependent variables such as rotation and opacity. We obtain these tracks by taking the output data file produced by the STELLAR program and then pass it through the CAPS code used in Smith, 2014 to obtain the temperature of the core as this is not exclusively output from our STELLAR code.

3.2.3 Mass Luminosity

In recent years, there has been a tendency to record luminosity as a function of the clump mass. This method is effective in showing the evolutionary stages and then the path onto zero age main sequence and the final mass of which it'll reach it at. The track can be broken down into two stages, the pre-main and main sequence paths. A vertical line represents the growing luminosity of the embedded protostar as the mass of the system (star and molecular cloud) remains relatively constant. This growing luminosity is an evolutionary aging technique. As the star reaches main sequence the cloud is dissipated through various processes including molecular outflows. This

second stage is shown by luminosity remaining relatively constant and the mass decreasing, shown by a horizontal plot. The luminosity of clump and mass of clump are found to be easily measurable with modern telescopes, as such large quantities of new data are available to overlay on the track plots to provide comparison.

Chapter 4

Results

Which accretion model is most concurrent with observational data? This question is hard to answer because of the vast differences between reality and our isolated single star scenario. However we can still try to find significant data points, such as the model that has a greatest swelling radius and or, greatest peak luminosity. By mapping these as reference points we can determine if there is correlation to observation.

We recognise that protostellar accretion can collapse or end at any stage if the mass supply is cut off. As such we must posit the question of the effects of rapid shutoff during a key phase of the evolution. Does the result of cutoff during the swelling or contraction phase lead to significant differences in tracks or its (spectral, evolution track) signature.

Whilst the model we use is more advanced than the likes of classic isothermal collapse, it is not fully inclusive of new research into star forming environments. More recent findings have shown giant molecular clouds are tend to have long reaching roughly cylindrical arms that mass will flow along with protostars and their clump flowing too. As such the filaments feed the clumps and the clumps feed the protostar, this dynamic process will significantly change the gravity, density and opacity of the protostellar clump. As such a higher mass star at an instantaneous point in time would be forming from a lower mass clump than our model suggests. So we must address the issue, is static spherical modelling a good enough representation of star formation?

Does a single base accretion rate apply throughout the entire protostellar evolution phase? Do protostars accuse mass using just one method, for all stages of evolution? We understand that stars form in dynamic regions,

where the current state of the protostar will give varying effects on its surroundings through the use of radiative feedback and jets, then we must also question if these effects can have a large enough impact on the envelope as to change the accretion rate. Does our 2d model, demonstrate these effects. Is the space-time grid large enough to encapsulate the extent of protostellar feedback?

4.0.1 Notes

An overview table of each accretion method we modelled is presented before displaying graph form of the results from the tests. The tables help reference key values from each test and its corresponding series of graphs. The tables are condensed versions of the complete sets of data which can be found in the digital appendix.

The figures of evolutionary tracks shown in the results section are to give an overview of the data produced in this research. The range of star masses produced is across three orders of magnitude. All the tracks produced can be found in the digital appendix, whilst all are not required to understand the results they may still be of interest.

4.1 Mass Radius

Here we compare the results from all four accretion models across a range of masses for the radius of protostar as a function of the mass. By plotting the tracks for all methods on one diagram we can easily spot significant differences between them. The final masses stated in the following tabled data is rounded to the nearest integer for ease of referencing between each model, the true masses differ by $\approx 1 - 5\%$.

Table 4.1 shows the final radius and its corresponding mass. It is evident that once a protostar has ended its accretion phase, the final radius is correlated to the final mass regardless of the accretion process. This can be seen for all results where each of the model's final radii are all within $< 5\%$ of each other. The only exception is $100M_{\odot}$ power law result of $34.32R_{\odot}$ which is $\approx 12\%$ less than the constant accretion model $38.92R_{\odot}$.

Final Mass (M_{\odot})	Accretion Method's Final Radius (R_{\odot})			
	Accelerated	Constant	Exponential	Power Law
1	2.48	2.50	2.48	2.50

100	664.08	589.33	662.64	819.32

TABLE 4.2: The data table of final mass and peak radius achieved using the respective accretion method. The masses highlighted here are a selection of relevant data points to the graphs featured. Full data available in the digital appendix.

Table 4.2 shows how significantly larger the radius of the protostar is during the accretion phase is from the final radius. The stars that undergo the swelling phase exacerbate this difference.

Figure 4.1 shows the accelerated accretion sharply swelling at approximately the $5M_{\odot}$ point, much before the other methods of $9 - 10M_{\odot}$. However it can be seen that the accelerated accretion sharply swells later than the others in the lower mass scenarios, figures 4.3, 4.4.

The transition between no swelling occurring to a full swelling phase occurs at masses between $4 - 8M_{\odot}$ as shown by figures 4.5 - 4.7. This also correlates to a jump in peak radius over the 5 and $10M_{\odot}$ data points shown in table 4.2. Note, the swelling phase does not begin simultaneously for each accretion method of same final mass. The swelling phase also holds up over different mass ranges; shown clearly in figure 4.3, the power law and exponential have higher peak values but radius drops at a lower mass,

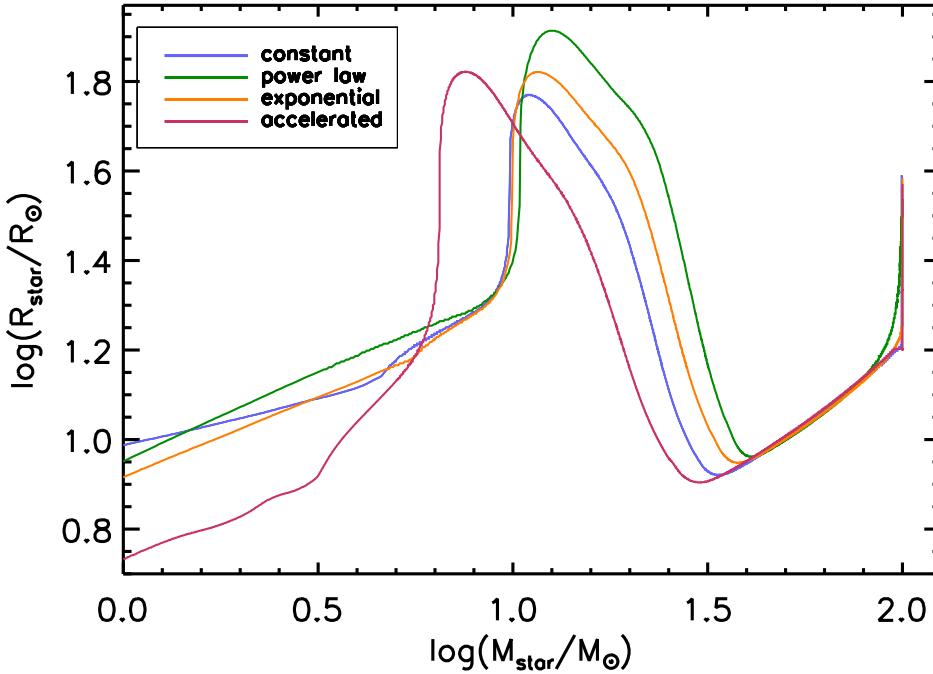

FIGURE 4.1: The radius tracks for protostars of final mass, $100M_{\odot}$. All four accretion methods are coloured accordingly as found in the legend.

whereas the drop occurs at a higher mass for the constant and accelerated models. As questioned earlier it can be seen over the range $5 - 10M_{\odot}$, the accretion phase ends during the Kelvin-Helmholtz contraction phase resulting in a drop in radius until the program ends. The higher mass stars continue to accrete mass during and after the contraction resulting in the star partially gaining back the radius lost, figures 4.3 & 4.1.

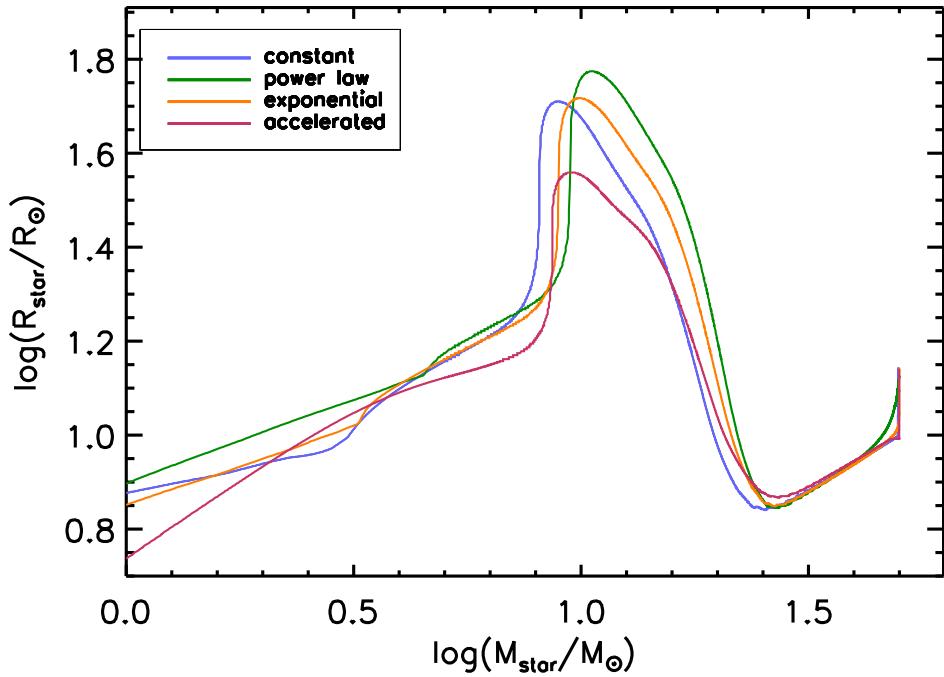

FIGURE 4.2: The radius tracks for protostars of final mass, $50M_{\odot}$. All four accretion methods are coloured accordingly as found in the legend.

4.2 Theoretical Hertzsprung Russell

We aimed to use the H-R diagram as another indicator to potential significant points in the evolution of protostars. Here we plot the protostellar models individually to keep the track simple to follow and avoiding multiple overlapping points when using group plots. The temperature is not a direct output from the STELLAR code so we use the results given and calculate the temperatures using the CAPS code from Smith, 2014, the result is effective.

4.2.1 Constant Accretion

This section shows the resultant H-R tracks for the constant accretion model.

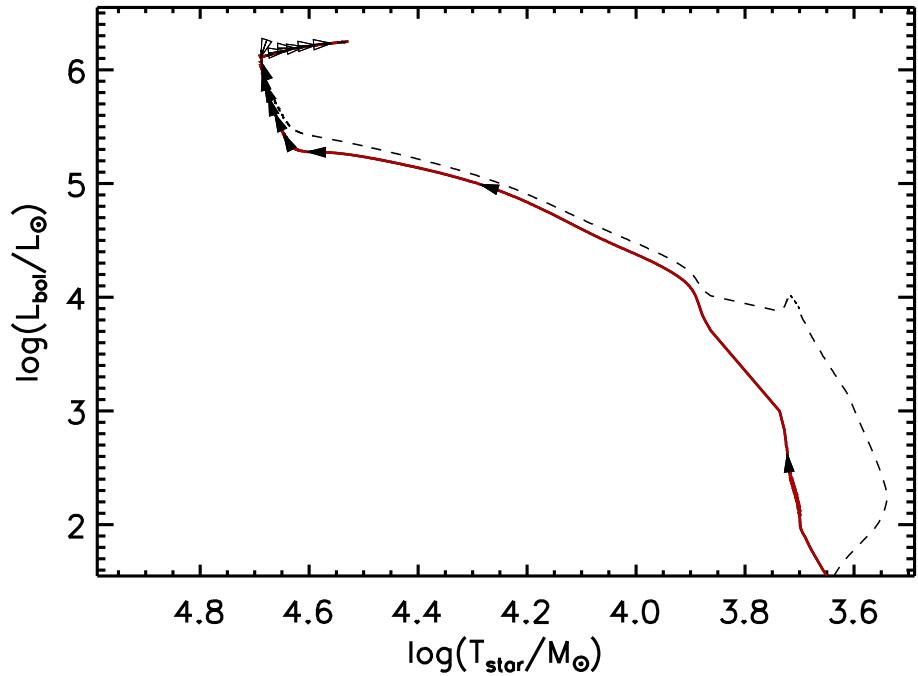

FIGURE 4.9: The H-R track for a star of $100M_{\odot}$ final mass using the cold constant accretion method. The dashed line represents the total luminosity and the solid coloured line represents the core luminosity.

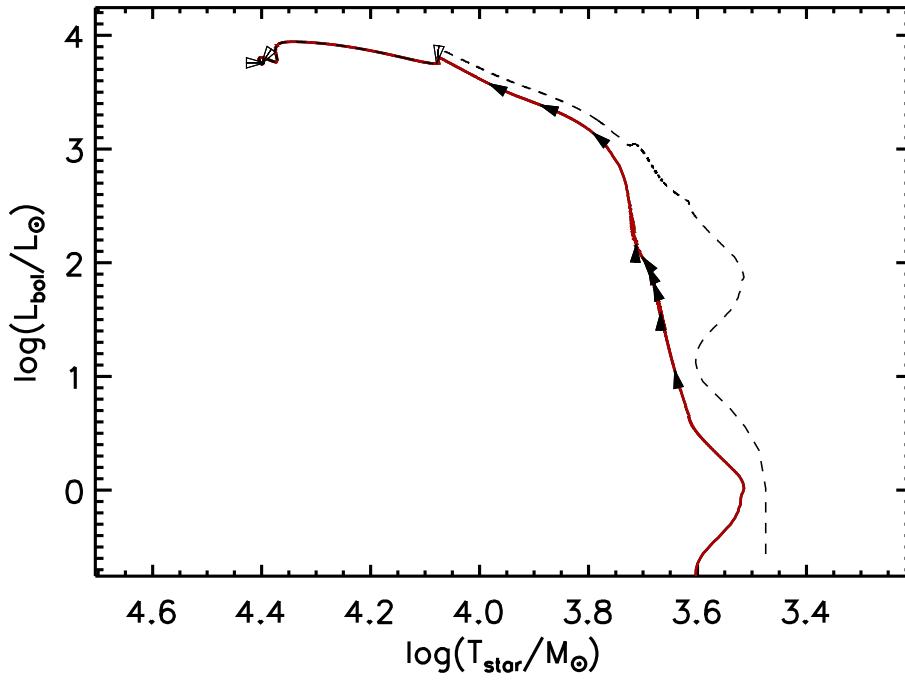

FIGURE 4.10: The H-R track for a star of $10M_{\odot}$ final mass using the cold constant accretion method. The dashed line represents the total luminosity and the solid coloured line represents the core luminosity.

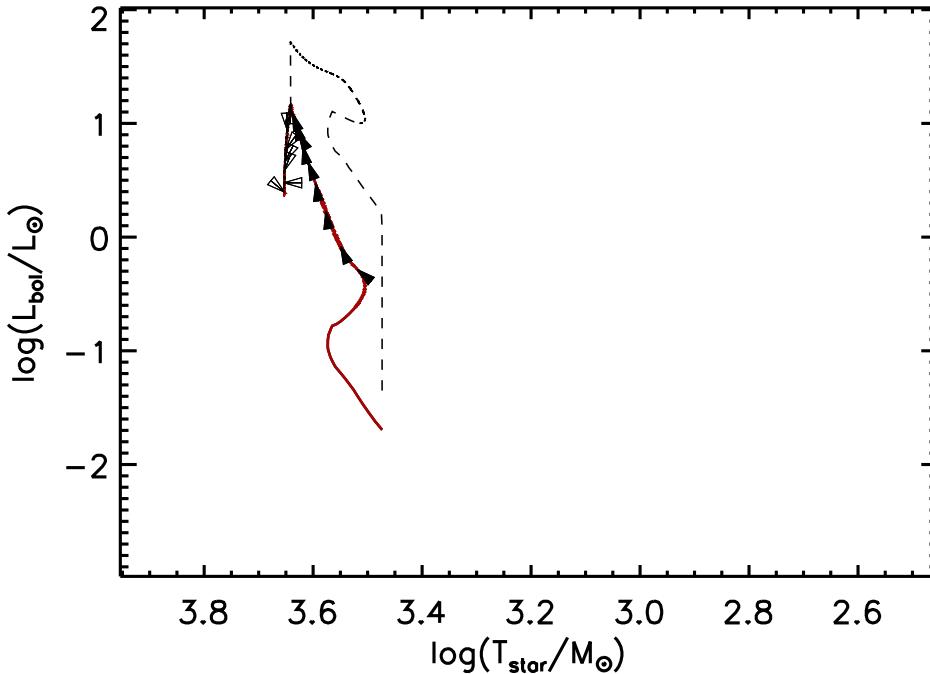

FIGURE 4.11: The H-R track for a star of $1M_{\odot}$ final mass using the cold constant accretion method. The dashed line represents the total luminosity and the solid coloured line represents the core luminosity.

4.2.2 Accelerated Accretion

The following section contains the H-R tracks for the accelerated model.

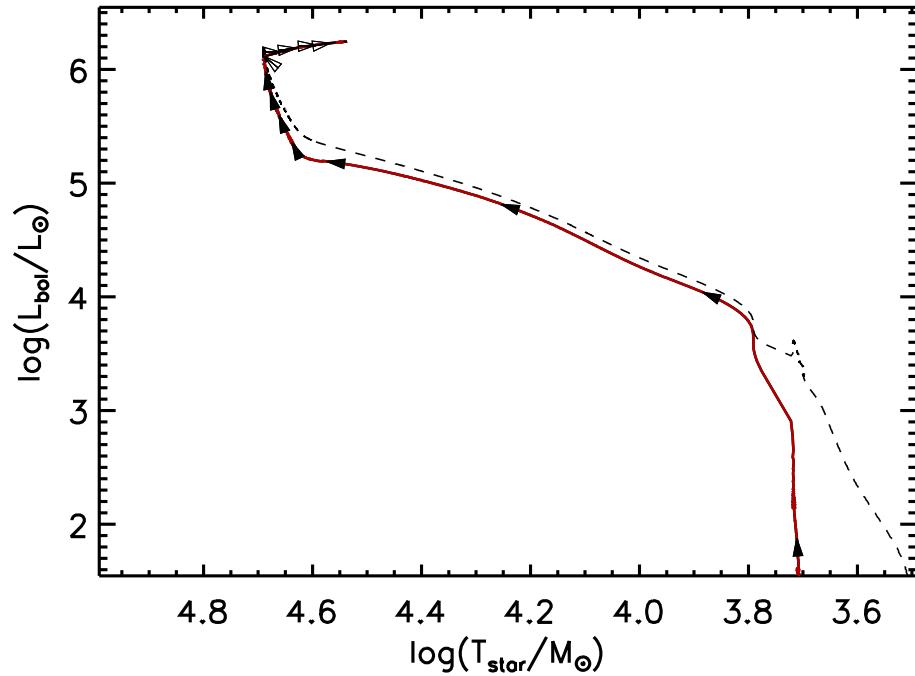

FIGURE 4.12: The H-R track for a star of $100M_{\odot}$ final mass using the cold accelerated accretion method. The dashed line represents the total luminosity and the solid coloured line represents the core luminosity.

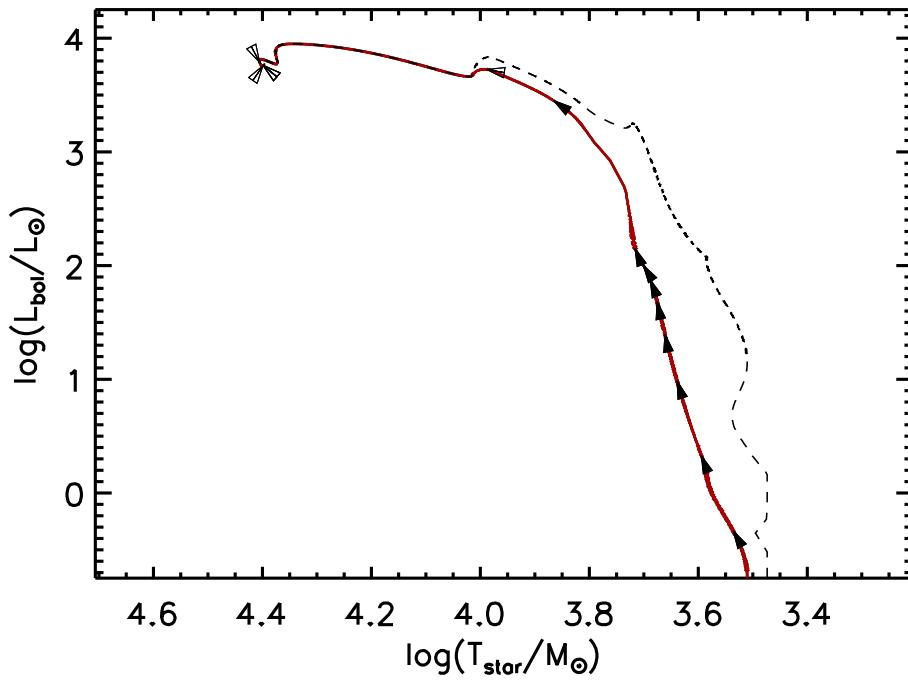

FIGURE 4.13: The H-R track for a star of $10M_{\odot}$ final mass using the cold accelerated accretion method. The dashed line represents the total luminosity and the solid coloured line represents the core luminosity.

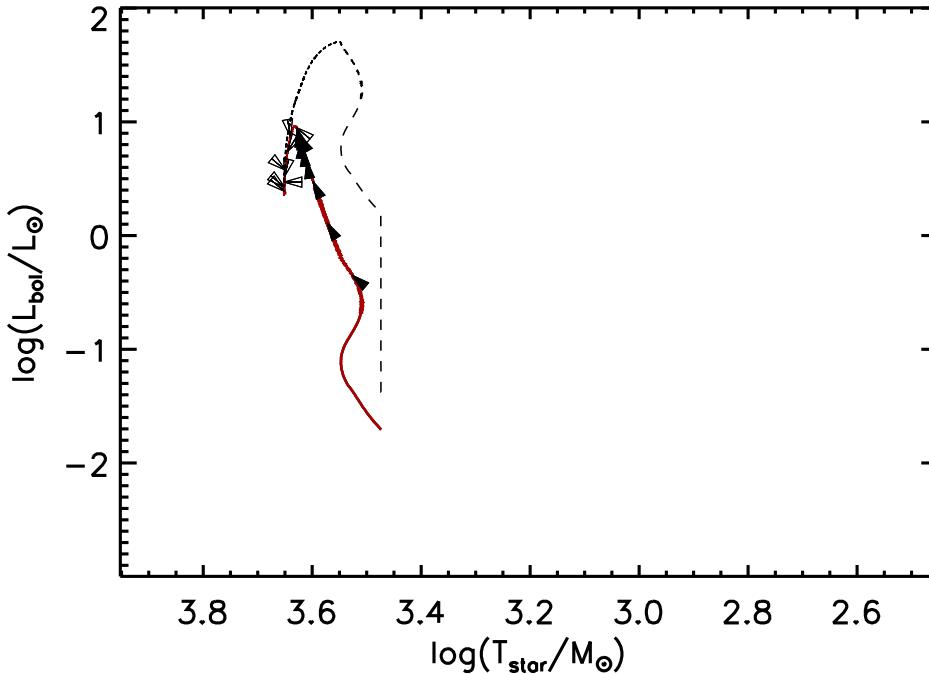

FIGURE 4.20: The H-R track for a star of $1M_{\odot}$ final mass using the cold power law accretion method. The dashed line represents the total luminosity and the solid coloured line represents the core luminosity.

4.3 Mass Luminosity

We plot the clump luminosity - clump mass relation with observational data overlaid. We calculate the clump mass from the stars final mass as using a modified version of equation 5 found in Molinari et al., 2008, the modification as defined in Smith, 2014 is given.

$$M_{cl} = \log(2.0) + 0.55 + 1.41 \times \log(3 \times M_f) \quad (4.1)$$

The result is a clump mass of ≈ 4.7 times greater than the final mass of all stars within the cluster including the mass loss from jets. We also include recent ATLASGAL data provided by Urquhart et al., 2014. The Urquhart data provides information on large number of stellar objects which primarily include intermediate to high mass stars found in the region between $280^\circ < l < 350^\circ$. We include dashed straight lines on all the plots which represent fixed ratios of 0.1, 1, 10 and, 100 luminosity to mass. These are centred at $x = 0, y = 1$ on the log scale axis, as this fits well with the observed data as shown later.

4.3.1 Constant Accretion

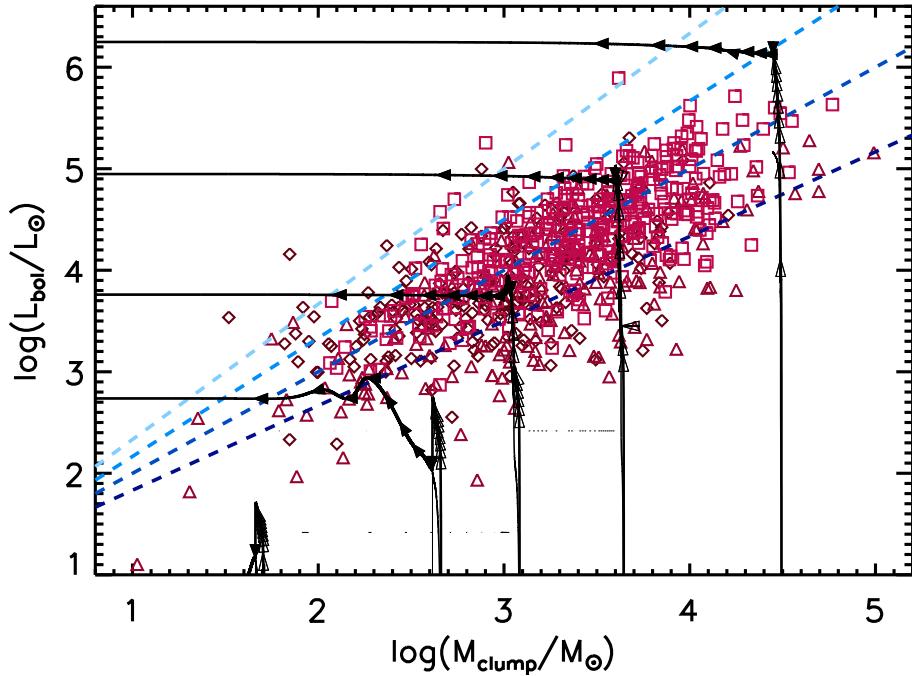

FIGURE 4.21: The Mass Luminosity tracks using the cold constant accretion method. The final masses of the stars associated with tracks from left to right, $1M_{\odot}$, $5M_{\odot}$, $10M_{\odot}$, $25M_{\odot}$, $100M_{\odot}$.

4.3.2 Accelerated Accretion

4.3.5 Clump Luminosity Clump Mass Distribution

Earlier we discussed the use of the luminosity mass diagram as an evolutionary aging mechanism. We aim to compare the model to the same observational data from Urquhart et al., 2014. We have to make an assumption of the observed data that allows the comparison to occur.

The instantaneous observation of a single stellar object provides very little information of the long term evolution of stars. Even extended observation times on the order of human lifetimes of a single star would still only offer a small amount of information. As such we implement a logical assumption that overcomes the time constraint. Given a large enough volume of observed objects the resultant data will be a fair distribution and provide a good representation of all stellar stages. A consequence of this is that rare events are perhaps not rare in occurrence but are just short lived events and less commonly observed.

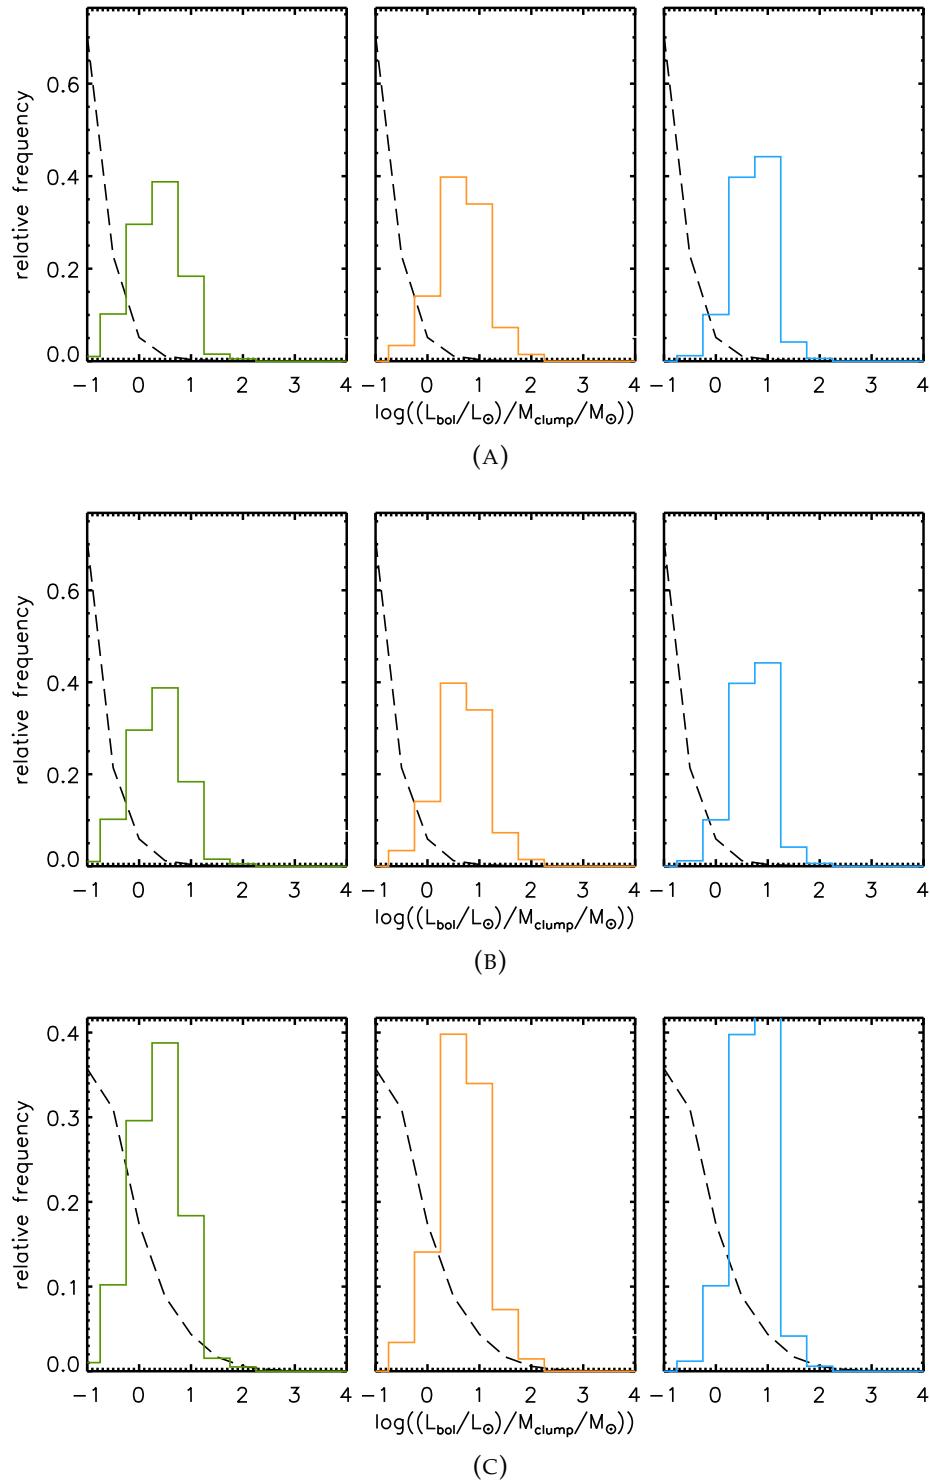

With our model data we find the luminosity mass relation of the star at each iteration. As such our model gives 30,000 ratios at equidistant time intervals; by ‘binning’ the ratios as done with the ATLASGAL data the resultant distribution of frequencies are representative of the time spent at each ratio bin. The discussed assumption allows us to compare the two different data sets, as such we plot the model histogram over the observed data histograms for each object type. We achieve this by assuming that the chances of observing a star at any stage of the evolution are equal. By then binning equidistant time periods on our tracks we can calculate the number of objects in each bin to see how well our model compares to observation. We convert both model and observed data to relative frequency so they can be compared on the same axis scale.

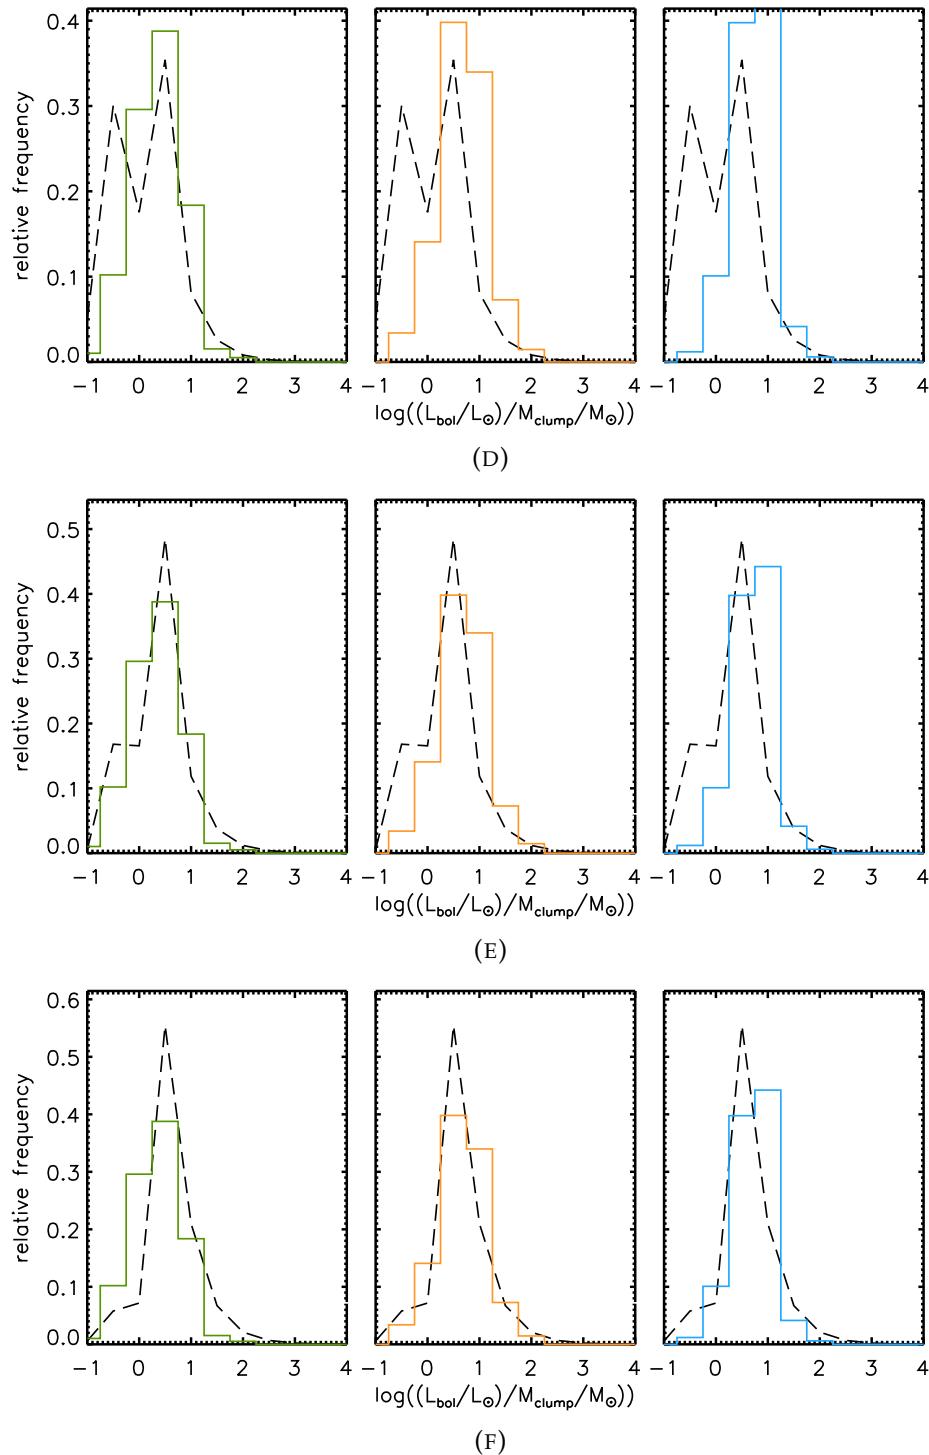

4.3.6 Smooth Accretion results

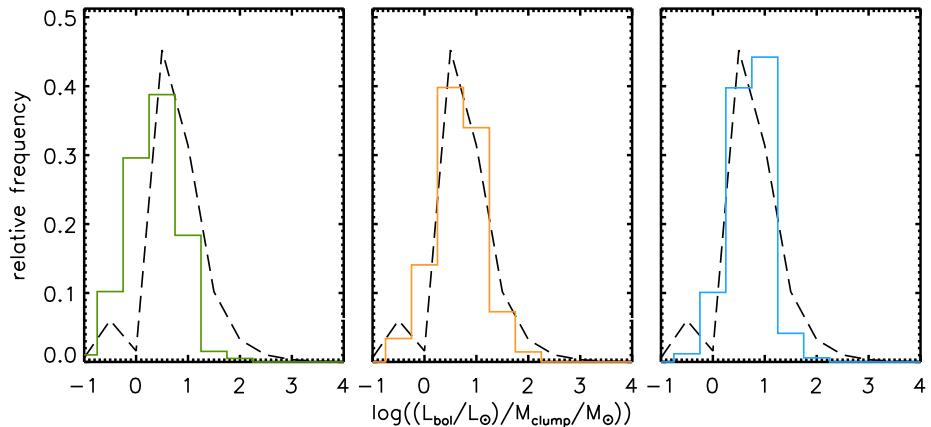

The following sections contain the histogram plots for the accretion model results of final masses. Each set of three figures has the model tracks (dashed line) and one observed object type. The left column contains the MMB distribution (green), the central column contains the YSO distribution (orange) and, the right column contains the HII distribution (blue). The models used from top to bottom are final masses; 1,2,4,5,6,8,10,15,20,25 and, $100 M_{\odot}$ respectively. This pattern is repeated for each accretion type.

4.4 Episodic Accretion Bursts

We incorporated episodic accretion bursts as recent findings have shown their significance in the protostellar growth process. The process of applying bursts by using a modulo function was successful and required minimal alterations to get the stellar code to work with it.

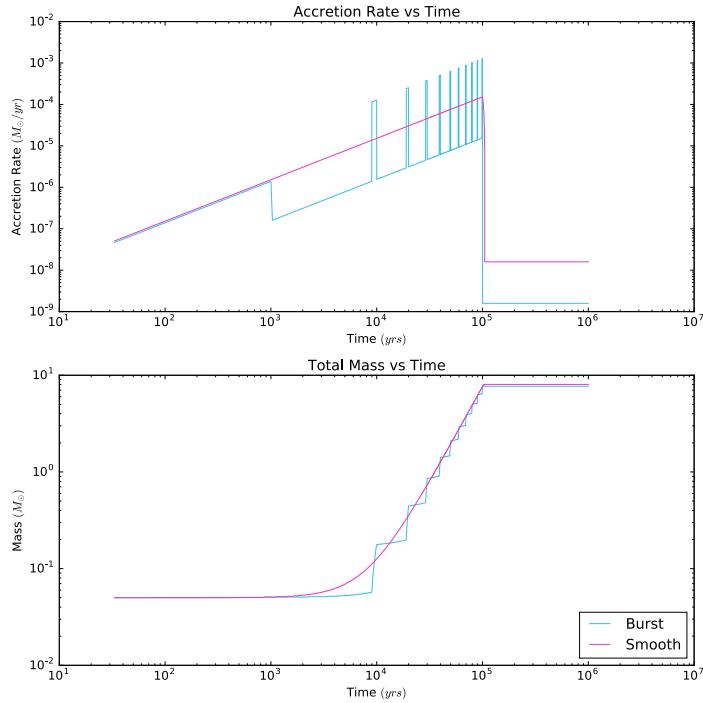

FIGURE 4.29: The accelerated accretion rate over time for both the smooth and burst accretion models. The final mass achieved is shown in the lower graph.

Figure 4.29 shows the accretion rate and mass versus time for the accelerated accretion model with and without bursts, as an example of how the process works. The accretion rate without bursts can be viewed as a base in which the modulo function overlays to get the burst result, the result is an identical final mass. It was found that the STELLAR code would become unstable and cease running when exceeding a certain mass. The episodic accretion rate during a high phase is nearly an order of magnitude greater than the smooth accretion rate at the same time frame. As such when trying to produce a $100M_{\odot}$ star the rate will peak at equivalent rate for a $1,000M_{\odot}$ star in the base model. It was found that the code was only stable for producing stars up to $\approx 20 - 25M_{\odot}$ masses. As such the following results will reflect this.

Final Mass (M_{\odot})	Accretion Method incl. bursts Final Radius (R_{\odot})

4.4.1 Mass radius

We again table the important radii data and mass data for all episodic accretion models to view points of significant interest, noting the accelerated model could not complete the full evolution at masses greater than $15M_{\odot}$.

Constant Accretion

The following tracks show three tracks of different stellar masses all using the same accretion model, differing from the previous tracks that include all models for the same mass. The inclusion of bursts results in large overlaps between tracks making it difficult to distinguish the tracks notably more so when the tracks are of similar masses.

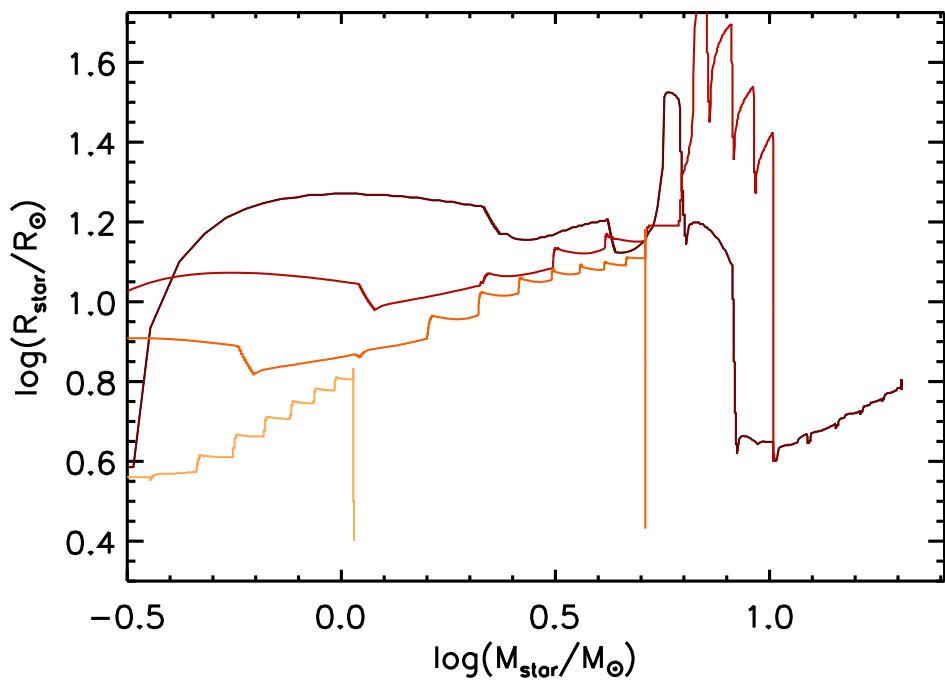

FIGURE 4.30: The radius as function of mass tracks for cold constant accretion with episodic bursts. The tracks stars of final masses $1M_{\odot}$, $5M_{\odot}$, $10M_{\odot}$ and, $20M_{\odot}$ respectively.

4.4.2 Episodal theoretical H-R

We post the tracks as individual results as the complex tracks become hard to distinguish if grouped. The episodic bursts greatly adds complexity to the path making it harder to understand.

4.4.3 Constant Accretion

This section shows the resultant H-R tracks for the constant accretion model.

4.4.9 Luminosity Mass Distribution

This section follows the same layout as the smooth clump luminosity clump mass but using the episodic burst models. It is important to notice how minimal the differences of the smooth and burst accretion methods; very similar distribution curves but the burst methods showing slightly greater frequencies in the greater luminosity mass ratio bins. This is more noticeable in the lower final mass models.

Constant

Chapter 5

Discussion

5.1 2D Hydrodynamic code

Before discussing the different observations and results of our model, we must first discuss what is realistically feasible to be within the code and its limits. The STELLAR code was found to be fairly fragile, often stumbling at the intersections of accretions rates. The cause being the large changes of internal structure that occur with a change in energy input. If the number Henyey iterations allowed within the code was increased and the minimum internal time step increment decreased, it is likely that the code would find convergence and continue without failing. However, this would largely increase total program run time, especially when using the burst model, which is not ideal for testing conditions in allotted time frames.

As briefly mentioned earlier; the older Fortran 77 code is limited in its functionality, for instance evaluating complex integrals is not easily possible, such as solving the gamma function involved with the power law model. Another flaw being the seventy two character limitation for each line which adds unnecessary complexity and point of failure. An update to a modern version of Fortran (90, 95, 2003 etc) would allow access to a wider range of libraries and improved functionality, which in turn could simplify the whole process of experimental testing. The added ability to include complex functions would also be useful and could help achieve more accurate results. Whilst conversion would be a cumbersome task the added benefit is likely worth making the change.

STELLAR is a spherically symmetric hydrodynamic code, in which it models a quartered section of the stellar space and then uses the axial symmetry to give a complete image. This may remove potential interactions

that could occur for a complete star. An approach such as that found in Hosokawa et al., 2016, whereby using the STELLAR code alongside a three dimensional hydrodynamic radiation model could be a good logical step to maximising effectiveness of this code.

5.2 General

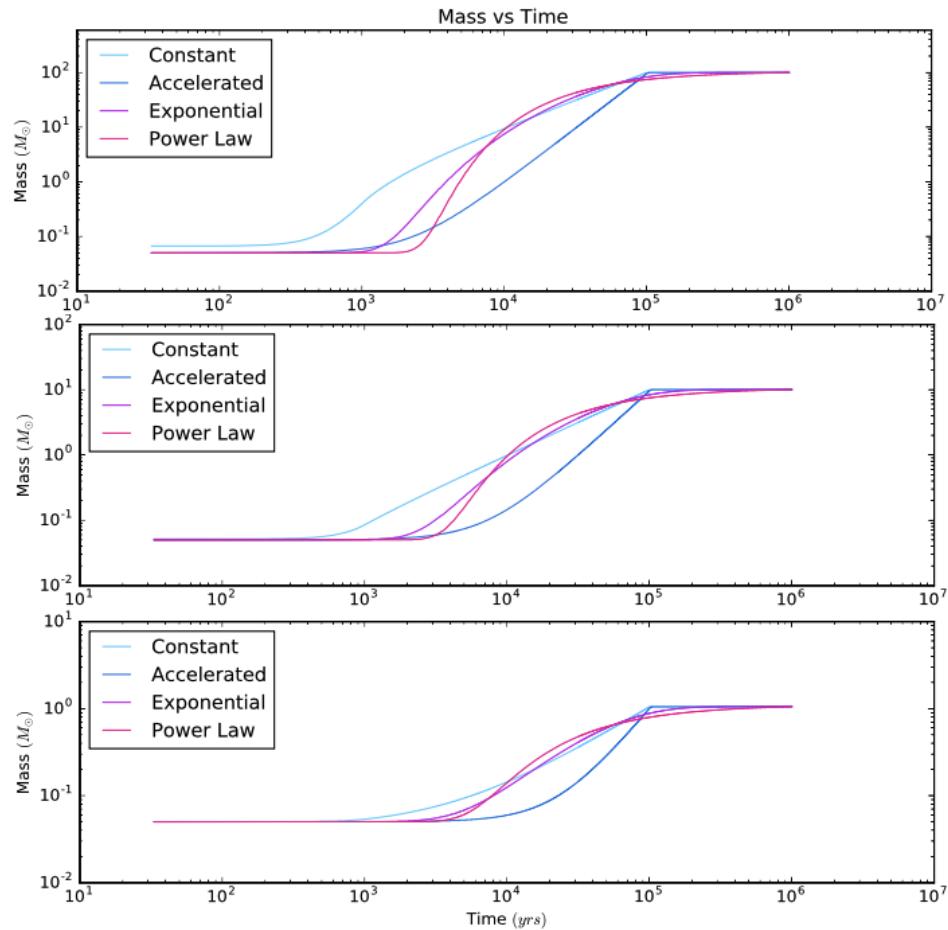

FIGURE 5.1: The four different models and the accumulated mass as a function of time. From top to bottom, the plots show the results of stars of final masses $100M_{\odot}$, $10M_{\odot}$ and $1M_{\odot}$ respectively

Here we include figure 5.1 displaying the mass accumulation as a function of time. The figure displays important characteristic differences between the models. The accelerated model in particular holds a much lower value of stellar mass for the majority of the accretion time compared to the other three models, where the other three models accumulate most of the mass earlier in the accretion phase. This is likely the contributing factor

to the differences in tracks found between the accelerated model and the others.

5.3 The Mass Radius tracks

Figures 4.1 through to 4.8 show the progressive changes in radius with the change in final mass. First noting that all models spend a large portion of the track on very similar paths, from the points of -0.2 to 0.6 $\text{Log}(M/M_{\odot})$. This is perhaps indicative of how all four models used in this paper each have counterparts of observational evidence. One exception we find is the accelerated $100M_{\odot}$ model in figure 4.1, as previously noted this is likely because of the accelerated models mass accumulation being weighted toward the later stages of accretion compared to the others, as such the early stage has a much lower radius. Secondly we can note that the swelling phase begins to occur in the Exponential and Power law models around the $5 - 6M_{\odot}$ final mass, 4.64.7 and the Accelerated and Constant models occurring around $6 - 8M_{\odot}$ final mass, 4.5. It can also be seen from the same figures, that even though the accelerated models swelling phase occurs at greater masses, the peak radius is greater than the other three models for mid range masses. These two points indicate that the swelling phase during evolution has a form of dependency upon the energy input, and not just the protostellar cores accumulated mass.

The $100M_{\odot}$ results, figure 4.1, show the exponential model reaching greater peak radius than the accelerated model. If the models greatest accretion rate and thus energy input, coincides with the beginning of the swelling phase, the result is a greater radius.

Lastly, we must note that the $100M_{\odot}$ mass stars, 4.1, continue to accrete after the Kelvin Helmholtz contraction phase. With between 50 – 60% of mass being gained after the contraction stage, the track is significantly different to the lower mass models, showing evidence that for massive stars there is a stage between the PMS contraction and ZAMS.

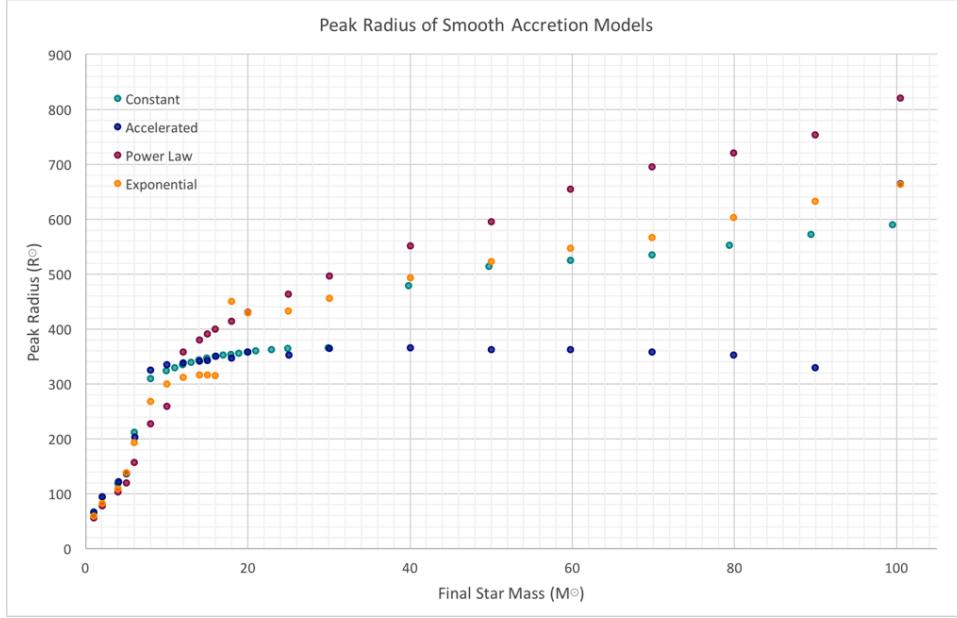

FIGURE 5.2: The maximum peak radius achieved for each of the smooth accretion models at each modelled mass. Note the accelerated model $100M_\odot$ result is obscured by the constant data point.

Figure 5.2 shows the variation in peak radii achieved across the complete modelled range of masses. The models show similarity in peak radius at low masses with distinction between the models becoming apparent once the swelling phase is fully established around the $8M_\odot$ mass point. The constant and exponential models share similar peak radii for masses $\geq 40M_\odot$, whereas power law is much greater and accelerated model is much less from the same point. The power law peak radii being much greater aligns with the idea that the stellar evolution has a time dependent factor, where energy and mass input to the protostellar core will have a large affect on the tracks of the star. Leading from this, we can assume the power law reaches peak accretion around the time swelling occurs thus exemplifying the radius reached.

An approach of finding radii distributions for massive protostars as a function of their mass were possible, then each model would become apparent at certain boundaries. The power law for instance would have a distribution shifted toward a greater radius mass ratio compared to the others, and the accelerated would be shifted lower.

An interesting point is the display of two large jumps in peak radius for all the models but occurring at different masses. The first jump coincides with

the swelling phase as to be expected and can be seen by the difference in clusters between the $2M_{\odot}$ and $10M_{\odot}$ points. The second occurs at different points for each model; the constant model displays a jump between 30 and $40M_{\odot}$, the accelerated between 90 and $100M_{\odot}$. The power law is harder to notice but it occurs close after the establishment of a swelling phase, the 8 and $10M_{\odot}$ results are similar but the $12M_{\odot}$ result is much larger. The exponential jump occurs between the 16 and $18M_{\odot}$, noticing the small plateau between 10 and $15M_{\odot}$ points.

5.4 Hertzsprung Russell Tracks

We plot the bolometric luminosity against the star temperature to give an effective HR track. Aspects of tracks conform with expectation, we see the maximum luminosity reached by each star increases exponentially with mass, also the temperature shows a general increase with time as to be expected with stellar evolution. We note that the difference between solid line (star) and dashed line (accretion) luminosities show that the accretion luminosity is far more significant in the early stages of the evolution. The arrows on our temperature - luminosity figures display the accretion time at fixed intervals, with the tracks showing a tendency for the majority of track movement occurring early in the evolution and a stagnation once accretion ends. We can attribute this to being the bolometric luminosity of the star and cloud system. This remains relatively constant after accretion has stopped until main sequence is reached, this is a slow and long process which is not within the 10^6 yr time frame of most of our models. The $100M_{\odot}$ star model however has a sharp jump from 10^5 to $10^6 L_{\odot}$ which could be a signifying point of reaching main sequence.

Future use of similar tracks, finding the bolometric luminosity as function bolometric temperature rather than star temperature may be more beneficial. We can observe bolometric temperature directly whereas calculating the embedded star temperature will result in inaccuracies.

The theoretical HR tracks show the complexity of the time dependent relationship between luminosity and temperature for protostellar evolution.

We observe general trends across all models; the tracks will all move upward to greater luminosities with increase mass and time. The temperature tends to move to the left toward higher temperatures with the size of movement being mass dependent. This is comparable to the Henyey-Hayashi condition of establishing star type. We can see that the $1M_{\odot}$ results show a decrease in luminosity at the end of the tracks, whereas the $100M_{\odot}$ show a move up by about half an order of magnitude. The $10M_{\odot}$ results show little movement in luminosity at the end of the track. The episodic burst add fluctuations to luminosities and temperature throughout the track, with the final temperature and luminosity being almost identical to the smooth accretion tracks. The $10M_{\odot}$ power law bursts show a large time spent around $T = \log(3.6)$ before moving rapidly to higher temperatures. This is likely linked to how the bursts coincide with the swelling and contraction phases. The decreases in temperature toward the end of the tracks, in particular for the lower mass stars, occurs with the contraction phase where we know the clump is dissipated allowing for radiation to escape and thus reducing internal energy.

The HR diagrams are a good guide to how a protostar behaves and is a good addition to use alongside the other theoretical model outputs. However, evaluating temperature for observed protostellar cores is hard due to the diffuse nature of the core itself and surrounding molecular clump. Temperature is easiest to observe once the surrounding cloud has dissipated.

5.5 Clump Luminosity Mass Relation

We must draw upon the limitations of the comparisons made in this paper to the observational data in the clump luminosity as function of clump mass graphs. Whilst ATLASGAL is one of the most comprehensive studies of the Milky Way, it still holds a level of selection bias due to the fixed bandwidth of a telescope and also due to where and what is being observed. This is immediately obvious by the larger quantity of observed HII objects than the other two object types. This is justified by the nature of HII objects being brighter and therefore easier to observe. We normalise the data for each

object type, so the distributions of each can be compared with greater confidence. The naturally dimmer objects found in the infrared range are much harder to observe. A case where smaller protostars are greatly unaccounted for is plausible, in which the distributions of the YSO and MMB data could be far different.

We used Urquhart's ATLASGAL data Urquhart et al., 2014 in the clump luminosity to clump mass tracks as comparison. As such we evaluate the observed data to find correlation between the two variables.

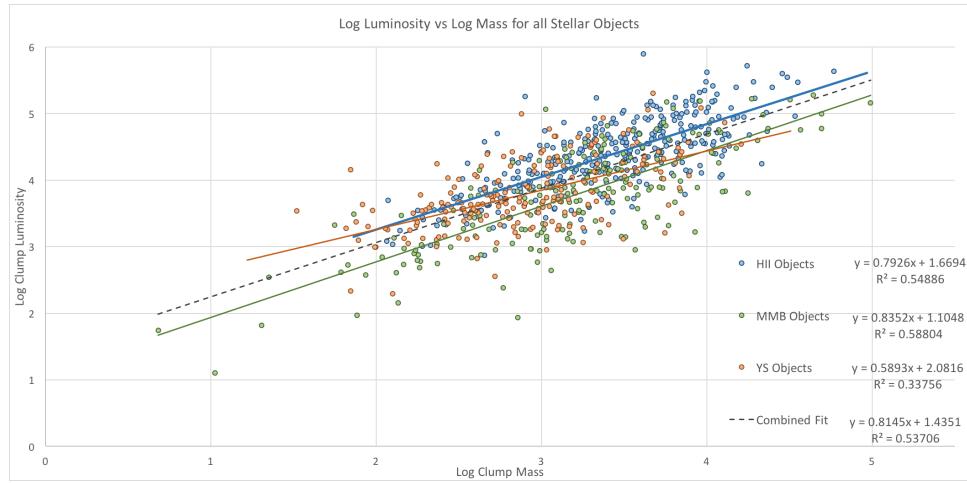

FIGURE 5.3: Urquhart et al., 2014 ATLASGAL observational data. Luminosity and mass are given in solar units.

We find linear least square regression for each data type and for the combined data set, shown in figure 5.3. The YSO data shows the weakest correlation of the individual object types with an R squared value of 0.338. We can likely attribute some of the variation from the line of best fit by the difficulty in observing the dimmer objects. The HII and MMB data shows a greater correlation both holding R squared values of ≈ 0.56 , meaning the line of best fit is a fairly good representation of the data. The R squared value for the combined data shows the YSO data has little effect on the regression as it is ≈ 0.55 , similar to the HII and MMB data. The YSO has a small effect due to the lower mass data being above the combined line of fit, and the higher mass being below, with the transition at almost exactly half way in the data seen at the Log Mass point of 3. In general, there is clear evidence of a positive linear correlation between the two variables, with an approximate ratio of $\approx 0.8L_{\odot} : 1M_{\odot}$. The other general observation is that

HII data tends to be in the higher clump masses, the other two data sets are found distributed across the whole range.

We used Urquhart's ATLASGAL data Urquhart et al., 2014 as reference in the clump mass - clump luminosity relation. To help understand how our model holds up in comparison, we evaluate the data in histogram form to see how well it follows a distribution function. Dividing the clump luminosity by the clump mass to give the ratio for each data point and then taking the log base ten ratio. Binning ratios in 0.5 intervals from negative one, to positive 2. We include figure 5.4 to show the difference in numbers

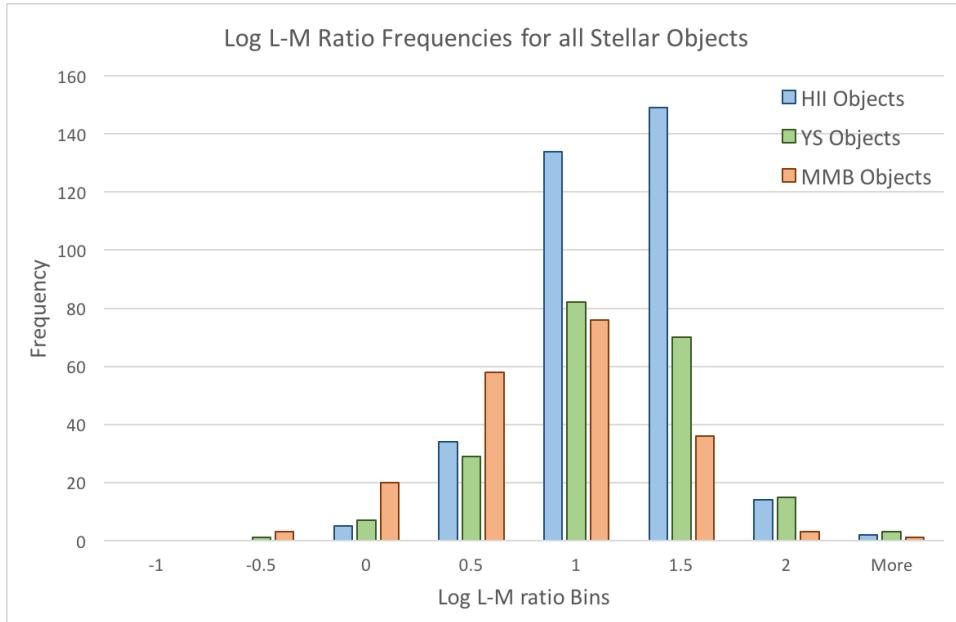

FIGURE 5.4: Frequency distribution of luminosity mass ratios from Urquhart et al., 2014 ATLASGAL data. L-M ratio is in solar units.

of each object type observed. As mentioned previously, the HII objects are naturally brighter and therefore easier to observe, thus why there is a 50% greater count compared to the YSOs and MMBs. This figure demonstrates the difficulty for a dedicated telescope in finding dimmer objects. As a result of this, the data cannot be truly evaluated as a distribution function until normalised. Figure 5.5 shows quite clearly the MMB data is more prevalent at the lower luminosity to mass ratio with a larger decline in relative number from the 1 to 1.5 bin. The YSOs show a similar agreement to this except with a lesser decline in the 1.5 bin. The HII objects show an increase in count rather than decline in the 1.5 bin, as to be expected with hotter objects

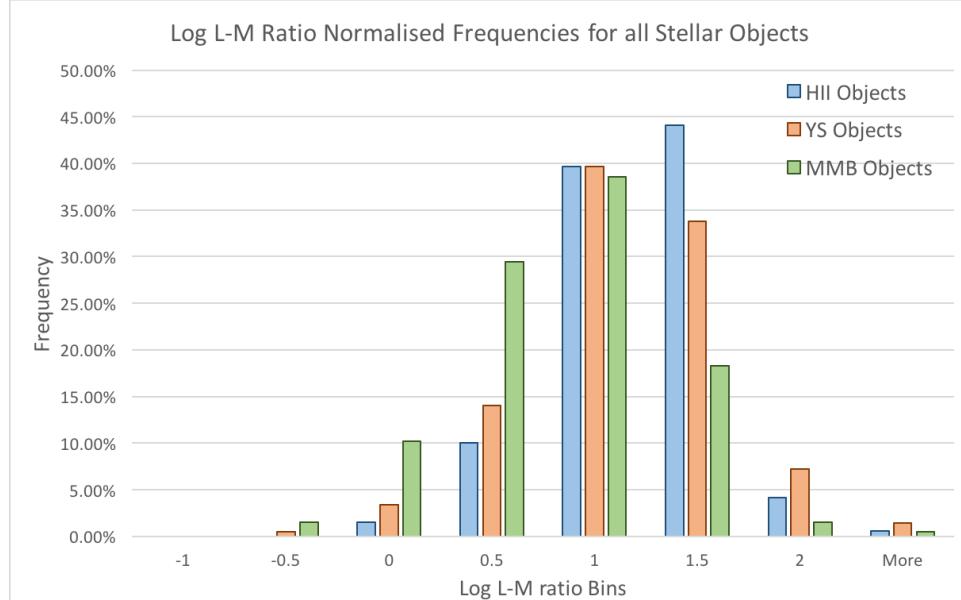

FIGURE 5.5: Normalised frequency distribution of luminosity mass ratios from Urquhart et al., 2014 ATLASGAL data. Each object type was normalised against itself only.

Object Type	Data Points	Mean Ratio	Median Ratio	Mean Squared
HII	338	0.9556	0.9958	0.9132
MMB	197	0.5926	0.6344	0.3512
YSO	207	0.9022	0.9176	0.8139

TABLE 5.1: Part one of tabled ATLASGAL observation data and key values found and used during Kolmogorov Smirnov test.

with greater luminosity for same equivalent mass. Figure 5.5 shows quite clearly there is some level of normal distribution function to the number of objects across the range, we attempt to quantify this using a Kolmogorov Smirnov single sample test on each object type.

From table 5.2 we can see that the standard deviation for each object type has a fair closeness to the mean, as we expect with a normal distribution. The HII data holds a smaller deviation which would correspond to the sharper peak observed in 5.5. The tabled data shows positive K-S scores for each object type which is found by subtracting the distribution function of

Object Type	Variance	Std. Deviation	K-S Score
HII	0.1631	0.4038	0.0325
MMB	0.2583	0.5082	0.0801
YSO	0.2474	0.4974	0.0639

TABLE 5.2: Part two of tabled evaluated ATLASGAL data.

the data away from the critical distribution function. A positive value is a good indication that the sampled frequency data follows a normal distribution curve.

From the distribution comparisons between model and ATLASGAL data, we can see the models obey similar normal distribution curves with the distribution being shifted dependent on mass. Generally, the lower mass models of $1 - 4M_{\odot}$ spend the majority of time in the lower luminosity mass ratio bins of -1 and below. With increased mass the distributions move into greater luminosity mass ratios.

The low mass models can attribute the majority of luminosity to the accretion, whereas high mass attribute it to the stellar core. The model star of mass $100M_{\odot}$, spends the majority of time at $\geq 1.5 \text{LOG}(L/M)$. An interesting feature to note is the $5M_{\odot}$ and some $6M_{\odot}$ models are bimodal distributions. The distributions show two distinct peaks in relative frequency an order of magnitude apart, from 0.5-1.5, with a large drop in between. This is likely due to these mid-range mass stars having similar timescales for the adiabatic accretion phase to the swelling and contraction phases.

The reason for the drop in luminosity between the peaks could be a result of the swollen cloud blocking the accretion and stellar luminosities. The stellar luminosity will increase but still be contained within the swollen cloud and then over a short time the KH contraction will occur, causing the jump in L-M ratio rather than a steady progression between the two.

We apply a two sample Kolmogorov Smirnov test to compare the two distributions of data and model to see which combinations show best alignment. The data is tabled in the appendix [A.1](#) through [A.6](#). The low and high mass KS tests show there is significant differences between the distributions meaning the two cannot be reliably compared, indicated by a value of one in the respective field. We can clearly see this in the distribution figures, where the high and low mass curves are at extreme ends of the scale, whereas observational data is fairly central. Leading from this then, we see some of the mid range masses show that there is statistically no significant difference between the two distributions. The YSO data found good

matches at final stellar mass $10M_{\odot}$ for all but the constant accretion models, and the MMB data had good matches at $6M_{\odot}$ for all but the power law model. The HII object data was found to have no matching model distribution, this however can be explained by our results being more sparse for higher masses and a match is likely to be found somewhere between 10 and $15M_{\odot}$ masses judging by figures presented earlier. Whilst this data on its own may not be of significant use as the models are of individual stars and the observational data is of all masses, the result of finding matching masses to the overall distributions could hold potential for IMF analysis. Our results show that MMB data has an equivalent L-M distribution of a $6M_{\odot}$ mass star. As such, by counting the easily observable high mass stars within a cluster and finding the resultant L/M distribution, then the more obscured and embedded low mass stars can be effectively counted by using the model $6M_{\odot}$ distribution result as a weighting function to the observed high mass distribution. The same process can be applied for each individual or a combination of object types.

5.6 Episodic Bursts

The burst accretion method has shown the protostellar peak radii achieved is much larger than the smooth accretion equivalents. Again showing evidence for the swelling phases occurring due to energy input rate and less so on the current mass. Another note to this is that if observational evidence does not conform to the peak radii achieved then it is likely the 90% – 10% ratio of mass accumulated in the high and low accretion states is incorrect. Further testing with our accretion model with different ratios could lead to a relationship between this ratio and the maximum radius and luminosity achieved.

As shown in figure 5.6, it is unlikely that episodic accretion that is perfectly modulated as used in our model is what occurs in reality. It is more likely that the bursts peak and curve down as radiation feedback would begin to slow the rate shortly after. An interesting extension to this model would be to establish a multiplicative factor to the accretion rate that combines a series of sinusoidal functions to provide a nearly random accretion

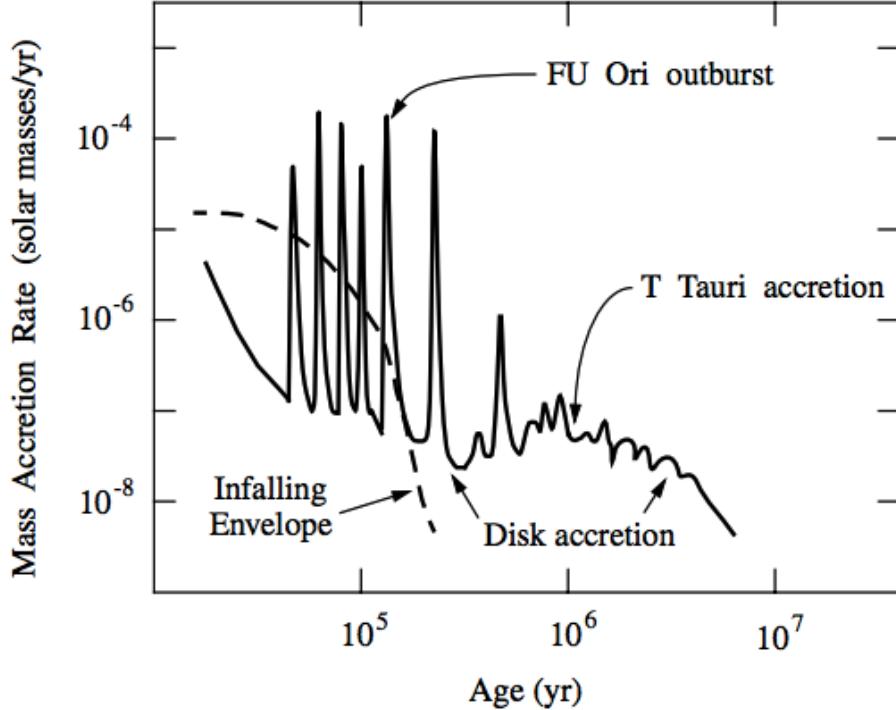

FIGURE 5.6: This figure is taken from Calvet, Hartmann, and Strom, 2000. The accretion versus time graph displays potential ideas on the evolution of disk accretion and the different phases that occur. Early infall burst accretion, moving to a more irregular ‘noisy’ disk accretion.

rate. In its simplest form an initial main sinusoidal function would establish the change between high and low accretion states, with further sine functions providing a ‘noise’ factor to the accretion as would be expected in reality. This would also require a more diverse final mass calculation.

In concurrence we modelled short accretion burst followed by a relatively long quiescent phase Smith et al., 2012. Recent findings however, have shown that the time frame of these bursts can vary from a few decades Audard et al., 2014 to several hundred years Vorobyov et al., 2013. Modelling both short cycle and long cycle bursts would be beneficial.

5.7 Early Accretion Cut Off

Previously we posed the question of accretion cut off during swelling or contraction phases and its effect. Seen in the mass radius tracks for $6-10M_{\odot}$ masses, the accretion cuts off during these stages as seen by the sharp decline in radius. Looking at the episodic $8M_{\odot}$ mass radius tracks, the change

to low accretion phase causes a very similar drop in radius from the peak. The accretion cut off has little effect on end result, in which the primary factor of final radius and luminosity, is the mass. This may change with a hot accretion method where internal energy would be greater. The $100M_{\odot}$ mass radius tracks show a more gradual decline in radius with the eventual growth again as the mass is still increasing. How much influence of this effect is due to the continued accretion or just a consequence of being a massive star is hard to determine.

5.8 Molecular cloud influence

Here we define a scenario of cylindrical filaments as a primary property of GMCs with star formation occurring within these filaments. Figure 5.7

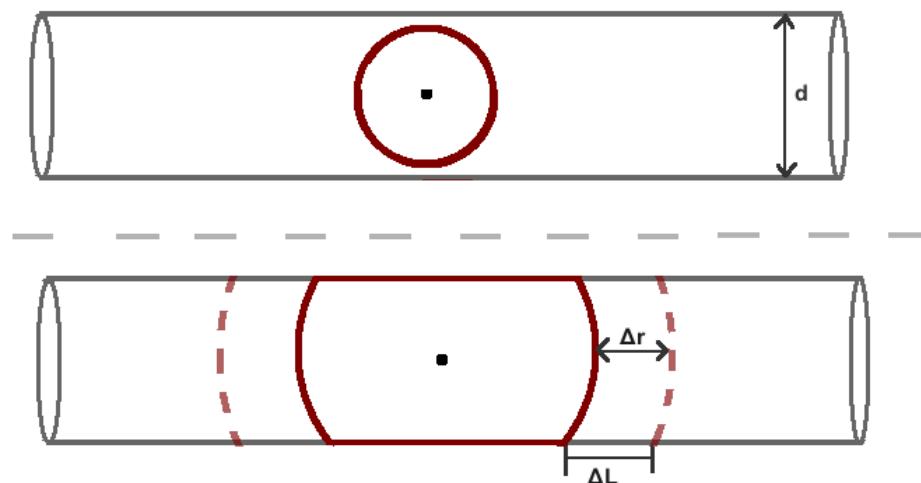

FIGURE 5.7: An ideal scenario depicting the growth of a sphere of influence by a protostellar core in a cylindrical filament. The black dot serves as a central point for a protostar. The red lines represent the sphere of influence, with dashed line as potential future sphere. d is the diameter of cylinder, Δr is the change in radius, ΔL is the change in length.

shows simplified growth of protostellar sphere of influence. Initially, in the upper figure section, the growth of the sphere is unaffected by cloud shape and so the mass encapsulated by the SOI grows proportionally to the volume of the sphere. Once the SOI diameter exceeds the diameter of the filament, the mass encapsulated will no longer be proportional to sphere volume but to the volume of a cylinder, as shown in the lower section of

the figure. Protostellar SOIs would have a very large radius of curvature, so the curve of the SOI could be approximated as a flat disc growing along the length of the cylinder. The result being mass encapsulated grows proportional to $\pi(\frac{d}{2})^2$ when $r > (\frac{d}{2})$, and the SOI grows at a rate proportional to the speed of sound in the molecular cloud. Include the collapse across the width of the filament would result in some time dependent differential equation that requires further analysis than suggested above. The scale of this gas envelope is much greater than the size of an accretion disk which would be around the central protostellar core. We know that the envelope mass slowly feeds onto the accretion disk, which in turn feeds the protostellar core, Kenyon and Hartmann, 1995. There are questions that remain. How does the envelope feeding the accretion disk affect the accretion rate onto the core from the disk? What orientation does the accretion disk take, relative to the filament? Can this be incorporated into the model we used?

5.9 Other comparative works

Hosokawa et al., 2016 has shown relatively slow accretion of $< 50M_{\odot}$ stars in the primordial era, where stars stop accreting at the Kelvin-Helmholtz contraction phase due to the UV feedback. This does not seem to be the case for our findings as the high mass star models continue to contract and even continue accretion after the KH phase. However we do notice massive increases in radius for the episodic burst accretion, and we question if this is indicative of accretion slowing as energy cannot be radiated away quick enough. If our code is correct, then the slowing of $< 100M_{\odot}$ primordial stars shows the importance of establishing the correct chemical composition of protostars as the differences are significant. Thus when trying to model protostellar evolution as an aid in observation, the stars local molecular cloud composition must be evaluated.

Outflows will reduce the mass accumulated through accretion by a certain percentage, typically between 20 – 40%. Episodic bursts have been shown to contribute to a significant drop in bipolar outflows corresponding to when a burst has occurred. However as accretion bursts occur at a

stage in protostellar evolution where the accretion disk is fully established as the mechanism of mass accumulation onto the core. This is contradictory to bursts reducing outflow rate as an increase in accretion rate should correspond to an increase in the outflow rate governed by the protostars ratio of outflow losses. As such can we model a delay between the accretion onto protostar and the resulting increase in outflow mass.

Our findings have shown a clear distinction between two types of protostellar evolution; the lower masses where swelling does not occur, and higher masses where swelling does occur. We have also shown that the mass range at which this swelling occurs is not dependent on mass but likely on multiple factors notably energy input in the form of accretion rate and, at what stage the majority of mass is accumulated. This becomes problematic with comparing to observational data of protostars where the swelling radii overlap if compared at different ages. Multiple examples can be seen in the figures produced, notably figures 4.1 and 4.3 the $100M_{\odot}$ stars have a peak radius greater than the $50M_{\odot}$ stars, but both occur around the same $10M_{\odot}$ mass point.

Another limitation of this research has been the fixed scale of accretion time, observation has shown that massive stars could accrete in much less than the 1×10^5 yr scale we defined, and the smaller masses over much longer scales. If the accretion time is mass dependent then this could further alter the protostellar masses where swelling occurs.

Our model runs using the cold accretion mechanism, being the slow infall from the disk where energy is lost through radiative feedback. Further work using our model using hot accretion methods would help establish differences and provide evidence for and against each concept.

Chapter 6

Conclusion

Our research has shown the validity and value of computational modelling. The results build upon previous stellar evolutionary codes by showing more detailed paths taken in each type of evolutionary tracks studied. Achieved through smaller time steps and convergence modelling of a complete stellar structure.

The research has made first steps toward finding valid methods of comparing theoretical and observational data and to try make conclusions from them. In doing so we show the importance of simulations and the extent of how much useful data can be extracted and analysed to provide useful information.

The updates made to the code will reduce total time requirement when running the program in future. The updates also provide a good groundwork for running similar accretion methods or building upon them, as the equations have already been successfully incorporated to main code.

The smooth accretion models serve as a good baseline for understanding stellar evolution. Running both models concurrently displays the effects that occur in smooth accretion models and how they translate into the burst models.

6.1 Summary of Findings

Our models clearly demonstrate the similarities in the evolutionary tracks taken between accretion models, in particular in the early stages of stellar growth. This similarity potentially holds key information as to why all the

accretion models in this research have observational support. The accelerated model shows the greatest differences to the others for early stages of evolution or at mid to high masses, and therefore holds a greater potential to be identified in observation.

We must note the second surge in peak radii achieved by each model as shown in figure 5.2. The cause is seemingly vague but it clearly occurs at different mass points for each accretion model and as such holds potential as a signatory feature.

The episodic burst tests have shown a blurring effect in the mass radius evolutionary track. The switching between high and low accretion rates causes large fluctuations in the radius of the protostar, an observed star with the same accretion properties could appear to be a large star in a low accretion phase or a small star in high accretion phase. The clump luminosity clump mass distributions however were better in comparing to observation. The results produce good distributions closely matching the observed equivalents. The episodic bursts compared to the smooth accretion distributions show the lower luminosity mass ratios are shifted up, but the overall distribution is still very similar for models of the same final mass. As such mapping clump luminosity as a function of clump mass has shown to be a powerful, relevant tool and, is suggested for use in others research of a similar nature.

We add minor additions to literature versions of the luminosity - temperature tracks, with the addition of episodic bursts showing again a blurring effect between the high or low state. We notice that early in the evolution, the bursts only have a minor effect on the temperature, indicating the protostar temperature is more dependent upon the long term evolution and not the short term accretion changes.

6.2 Future work

The work completed in this project has shown how diverse the STELLAR code can be. With many variables unchanged, a lot is left to explore. We know that the composition of GMCs vary, especially when comparing modern and early universe examples. The fractions of Hydrogen, Helium and heavier elements could easily be adjusted to observe changes in tracks.

This project exclusively worked using a cold accretion model, whereby the material in accretion disk accrued onto protostellar core via steady infall. The code contains an energy parameter which can be adjusted to easily switch to a hot accretion model. Both methods are still debated upon and the insight given by this code could be beneficial.

Further inclusion of other observational data of clump luminosities and masses appended to the distributions and tracks we produced would be beneficial. A focus on finding and including low mass objects would be beneficial as the ATLASGAL data used in this project lacks information in this region. As mentioned before, with more observational data and improving upon our models, it could prove useful for IMF research.

To produce a more realistic model, we should look to model a secondary function that simulates accretion disk growth from infalling envelope mass. Currently the model is an enclosed system where total mass remains constant, modelling the steady input of more mass into the system to simulate envelope accretion could produce interesting results that better align with other works.

As previously mentioned, the episodic bursts we simulated were an ideal scenario between two clearly defined states. A more realistic model using shorter and or variable time scales between states would be a good step to make. Developing the code to include a secondary function, which works with the bursts code but add small fluctuations to the total accretion rate would also be a good addition to the base code used in this research..

6.3 End

The research conducted in this project has shown the worth of hydrodynamic modelling and how with effective data analysis methods, results can be used alongside or compared to real observational data. The evolutionary tracks we produced show evidence for complexities that are not found in data due to the instantaneous nature of observations.

Hopefully the data presented here will prove useful for other works and fields of research, which will ultimately help in understanding our local cluster, galaxy, Solar system and our place in the universe.

Appendix A

Appendix

Included in the appendix is all the individual Kolmogorov Smirnov test results. The significant difference row is a choice result, a value of one shows there is a significant difference between distributions and a value of zero shows there is no significant difference in distributions. If the D-crit value is greater than D-stat value then a zero is given when the p-value is greater than 0.05. A value of one is given if D-crit is less than D-stat or the p-value is less than 0.05.
